WHITE, J. WILLIAM, M.D.

INDEX TO VOLUME CXIX.

Abbott, S. W. Some historical and statistical facts concerning the use of arsenic as a poison, 435.

Abdominal Surgery. A case of perforating wound of the abdomen inflicted by an ox's horn, Gratch, N. S., 252; abdominal surgery at the Massachusetts General Hospital, Warren, J. C., and Richardson, M. H., 472; two cases of laparotomy for extra-uterine pregnancy, 549, 551; résumé of two and one-half years' experience in abdominal surgery, Irish, J. C., 621.

Abortion. Durant, C. E., 232.

Actinomycosis. Eve, F., 165.

Adams, Z. B., Bradford, E. H., and Withington, C. F. Report on physical culture in schools, 179.

Adenoid Growths. On thoracic deformity produced by adenoid growths in upper pharynx, Loewenberg, B., 46.

Adler, I. Some remarks on akromeglia, 507.

Aged. Few drugs in treating the aged, 566.

Agnew, D. H. The relation of social life to surgical disease, 274.

Aitken, W. Address on pathology, 206.

Akromeglia. Some remarks on akromeglia, Adler, I., 507.

Albuminuria. The absolute and relative value of albumen and casts, and of renal inadequacy in the diagnosis and prognosis of diseases of the kidney, Edes, R. T., 361; the relation of albuminuria to life insurance, Tyson, J., 362; notes on albuminuria, Bisbee, A. B., 409.

Alexander's operation. The value of Alexander's operation for shortening the round ligaments estimated from the results of twenty-three cases, 556.

Allbut, C. Classification of disease by means of comparative nosology, 206.

Allen, C. J. Acute yellow atrophy of the liver, 408.

Anæmia. The pathology of pernicious anæmia, Hunter, W., 417.

Anæsthesia. Observations of the time and amount of ether required to produce anæsthesia, Lovett, R. W., 549.

Anatomy. Demonstration of a model of frozen sections of the arm, with remarks on this method of teaching anatomy, 245, 285; recent progress in anatomy, Dwight, T., 322; valves in the veins of the human intestines, Bryant, W. S., 400.

Animal Magnetism. Six cases of treatment with animal magnetism, Mason, O., 484.

Annus Medicus MDCCCLXXXVIII., 637.

Anthrarobin, Bronson, E. B., 337.

Antipyrine as an analgesic, Fiske, E. L., 34; antipyrine in seasickness, Fisk, S. A., 238; antipyrine in seasickness, Stephenson, F. B., 371; antipyrine as an analgesic, Egan, P. R., 466.

Antisepsis in typhoid, 165.

Apostoli. A visit to the clinique of Dr. Apostoli of Paris, Campbell, W. M., 202.

Appendicitis. Two cases of appendicitis, one fatal, Stedman, C. E., 241; a case of appendicitis, with autopsy, Warner, E., 404; a case of appendicitis in a child, Whitman, R., 551, 553.

Argyrism. A case of argyrism, Ivanikoff, 417.

Arloing. On the local and general means capable of arresting the extension of experimental tuberculosis, 184.

Army Medical Examination, 140, 142; army medical corps, 514.

Arsenic. On motor paralysis and other symptoms of poisoning from medicinal doses of arsenic, Putnam, J. J., 1, 10; arsenic poisoning through the maternal milk, Brouardel, 70; some historical and statistical facts concerning the use of arsenic as a poison, Abbott, S. W., 435; the chemistry of arsenic, Hill, W. B., 435.

Ashhurst, J., Jr. A contribution to the study of excisions of the larger joints, 362.

Athetosis. A case of athetosis, Pengra, C. P., 80, 81.

Atkinson, I. E. Address before American Dermatological Association, 355.

Babes. The bacterial associations of the tubercle bacillus, 184.

Bailey, A. C. The anatomy, physiology, and therapeutics of the pharynx, 410.

Baker, H. B. Classification of diseases, 559.

Baker, W. E. A case of chronic Bright's disease, 572.

Balzer, M. F., and Klumpke, A. The elimination of mercury, 95.

Bangs, L. B. Clinical observations of diseases of the testicles, 332.

Baumgarten, G. Disturbances to the heart rhythm, with reference to their causation and their value in diagnosis, 363.

Bayet. Induction of premature labor, 542.

Beach, H. H. A. A case of strangulated hernia, 251; two cases of carbuncle, 251; ovarian cyst, 253; tumor of the breast, 253.

Bibliography. Aitken, W., on the animal alkaloids, the ptomaines, leucomaines, and extractives in their pathological relations, 636; Allen, N., physical development, or the laws governing the human system, 185; Ball, C. B., the rectum and anus, their diseases and treatment, 412; Barker, A. E., jr., a short manual of surgical operations, 412; Beil, J., a manual of the operations of surgery, for the use of senior students, house surgeons, and junior practitioners, 287; Boston City Hospital, annual report for 1887, 18; Boyd, S., Druitt's surgeon's vade mecum: a manual of modern surgery, 40; Browne, L., the throat and its diseases, including associated affections of the nose and ear, 137; Brubaker, A. P., Quiz compends, No. 4; a compend of human physiology, 40; Bruck, L., guide to the health resorts in Australia, Tasmania, and New Zealand, 41; Brunett, C., the massage case, 114; Brunton, T. L., a text-book of pharmacology, therapeutics and materia medica, 610; Bryant, J. D., manual of operative surgery, 314; Butlin, H. T., on the operative surgery of malignant disease, 232; Carcousse, M., Hygiène Braëlite, 560; Christopher, W. S., chemical experiments for medical students, 612; Disinfection and disinfectants: their application and use in the prevention and treatment of disease, and in public and private sanitation, 411; Garmany, J. J., operative surgery on the cadaver, 287; Garland, G. M., the modern treatment of pleurisy and pneumonia, 40; Hamilton, A. McL., a manual of medical jurisprudence, with special reference to diseases and injuries of the nervous system, 18; Hartridge, G., the refraction of the eye, 41; Heath, C., lectures on certain diseases of the jaws, 412; Hewitt, G., the pathology, diagnosis, and treatment of the diseases of women, 40; Hirst, B. C., a system of obstetrics by American authors, 611; Holland, J. W., the urine and the common poisons, 612; Horwitz, O., a compend of surgery for physicians and students, 412; the index catalogue of the library of the Surgeon-general's office, number ix., 368; Jacobs, M. P., essays on hysteria, brain tumor, and some other cases of nervous disease, 43; Jenks, E. W., the disorders of menstruation, 389; Keating, J. M., and Edwards, W. A., diseases of the heart and circulation in infancy and adolescence, 17; Leuf, A. H. P., hygiene for base-ball players, 389; Livers, H. H. N., a practical text-book of the diseases of women; Massachusetts health report, 66; Medical News visiting list, 537; Meyer, E., a practical treatise on diseases of the eye, 41; Morrow, P. A., atlas of venereal and skin diseases, 17; Nettleship, E., the student's guide to diseases of the eye, 41; Physicians' visiting list for 1889, 612; Prescott, A. B., organic analysis: a manual of the descriptive and analytical chemistry of certain carbon compounds in common use, 39; Ranney, A. L., the applied anatomy of the nervous system, 113; Rolland, E., de l'epilepsie Jacksonienne, 437; Shoemaker, J. V., a practical treatise on diseases of the skin, 136; Stewart, J. S., physicians' and students' ready reference series: obstetric synopsis, 560; Stillman, C. F., the life insurance examiner, 559; Tyson, J., a guide to the practical examination of the urine, 41; Van Nüys chemical analysis of healthy and diseased urine, qualitative and quantitative, 41; Vaughan, V. C., and Novy, F. G., ptomaines and leucomaines, or the purefactive and physiological alkaloids, 636; Walshaw, W. J., surgery; its theory and practice, 161; Waxham, F. E., intubation of the larynx, 65; Wilde, B. G., and Gage, S. H., anatomical technology as applied to the domestic cat, 537; Williams, W. R., the principles of cancer and tumor formation, 110; Witthaus, R. A., essentials of chemistry and toxicology for the use of students in medicine, 636; Wood and Bache, the dispensatory of the United States of America, 560; Wyeth, J. A., a text-book on surgery, general, operative, and mechanical, 257.

Bile. Experimental researches relative to the action of medicaments on the biliary secretion, and the elimination by this secretion, 20.

Billings, J. S. On medical museums, with special reference to the army medical museum at Washington, 265.

Biography. Arnold, J. W. S., 442; Bartlett, F. D., 544; Bennett, A. W., 96; Cheesman, T. M., 69; Cochrane, J., 264; Dunn, W. A., 440; Fothergill, J. M., 72; Fraenenburg, R., 260; Garnett, A. T., 72; Gunder, L. D., 544; Guthrie, S., 21; Heard, L. G., 320; Jones, R. K., 566; Klinghammer, W. J., 348; Kneeland, S., 372; Lodge, G. H., 644; Nichols, J. R., 232; Quackenbos, H. T., 216; Raphael, H., 164; Reinfelder, M. J., 566; Sabin, R. H., 590; Sabine, T. T., 216; Salmi, T. T., 441; Sands, H. B., 515, 542; Sargent, J., 396, 512; Sinute, C. B., 544; Stone, H. O., 216; Thatton, W. M., 370; Townshend, G. D., 240; Tuck, L. W., 419, 420; Walton, E. W., 370; Warrington, J., 589.

Birdsall, W. R. Report of a case of tumor treated by hypnotic suggestion, 484.

Bisbee, A. B. Notes on albuminuria, 409.

Blake, C. J. A new form of clinical taming fork, 604, 606.

Blake, J. G. Intra-uterine fœtal deformities, 498, 504; neurosis of the bladder, 505.

Blodgett, A. N. Unusual susceptibility to sedative remedies, 201.

Boardman, W. E. Report of cases confined at the Boston Lying-in Hospital during the three months, January 1 to April 1, 1888, 196, 202.

Bohne, W. Handbook for young and old opticians, 41.

Bolles, W. P. Dermoid cyst, 605.

Bombaugh, C. C. The multiplication of useless drugs, 537.

Bone. A contribution to the study of bone repair, Miller, J. S., 158.

Booker, W. D. A study of the micro-organisms in the stomach and intestines in the summer diarrhœa of infants, 16.

Boston Dispensary, 370.

Boston Lying-in Hospital. Reports of cases confined, Boardman, W. E., 196, 202.

Bowditch, H. I. Tolerance and intolerance in medicine; codes of ethics, 536.

Bowen, J. T. Two forms of skin tuberculosis, 151.

Boynton, H. Hysteria, 417.

Bradford, E. H. Osteo-chondro-sarcoma of the leg, 108; two cases of incision into the hip-joint, with observations as to "distraction" in hip-disease, 147, 155; a case of laparotomy, 387.
Bradford, E. H., and Lovett, R. W. Recent progress in orthopædic surgery, 475.
Bradford, J. R. On the value of salt in the treatment of acute rheumatism, 67.
Brain. Three successful cases of cerebral surgery, Keene, W. W., 305; the topography of the brain, 162; brain surgery, MacEwen, W., 205; subdural abscess of the brain, Stokes, W., 618.
Breast. Tumor of the breast, 253; excision of the breast for cancer, Hodges, R. M., 617, 630
Breneman, an unusually rare case of plural births, 541.
Brigham, L. M. A report of a case of Tait's operation for removal of ovaries, 411.
Bright's Disease, a case of chronic, Baker, W. E., 572.
Bronson, E. B. Anthrarobin, 337.
Brouardel. Arsenic poisoning through the maternal milk, 70.
Brown, D. The arrest of secretions in the eruptive fevers, 509.
Bryant, W. S. Valves in the veins of the human intestines, 400.
Bryson, J. P., and Burnett, E. C. Clinical observations on gonorrhœa, with special reference to etiology, duration, and treatment, 331.
Buck, A. H. Reflex influences in the production of naso-pharyngeal catarrh, 87; a contribution to the anatomy of the elephant's ear, 111.
Bulkley, L. D. Dermatitis plantaris and palmaris, 343; the relations between the general practitioner and the consultant or specialist, 586.
Bull, C. S. A contribution to the treatment of membranous opacities in the vitreous, 88.
Bull, W. T. The physical management of typhlitis and perityphlitis, 309.
Bullard, W. N. Observations on the steadiness of the hand and on static equilibrium, 595.
Buller, T. A case of pulsating exophthalmus cured by ligature of the common carotid artery, 88.
Bulletins. An illustration of medical bulletins, 140.
Bundy, F. E. One, possibly two, cases of Graves's disease, 27, 36.
Burnett, C. H. A case of aural vertigo (Meniere's disease) relieved by excision of the membrana tympani and malleus, 86.
Burnett, S. M. An analysis of 576 cases of the refraction of healthy human cornea, examined with the ophthalmometer of Javal and Schidz, 89; models exhibiting refraction by cylinders, 111.
Burrell, H. L. Cases illustrating the use of compression after the method of Mr. Gamgee, 528; a few points in Macewen's operation for the radical cure of hernia, 545, 554.
Burrell, H. L., and Cushing, H. W. Report on progress in surgery, 246, 283.
Burt, F. L. Uterine hæmorrhages, 580.
Bustles. Bustles, 490; the bustle, 514.
Cabot, A. T. Case of laparotomy for tubercular peritonitis, 121.
Cænogenesis. Gegenbauer, 185.
Campbell, E. R. What constitutes irregular practice? 410.
Campbell, W. M. A visit to the clinique of Dr. Apostoli of Paris, 262.
Capron, E. P. A case of glioma, 110.
Carbuncle. Two cases of carbuncle, Beach, H. H. A., 251.
Cascara sagrada in rheumatism, Goodwin, H. T., 22.
Cerebro-spinal meningitis. Endemic cerebro-spinal meningitis, Townsend, C. W., 52; a case of cerebro-spinal meningitis, Jacobs, H. B., 57; two cases of spinal meningitis, Jackson, H., 58; a case of cerebro-spinal meningitis of the pneumonic type with painful joints, and worms, Mason, A. L., 62; two cases of cerebro-spinal meningitis, Grass, G. G., 131.
Channing, W. Massachusetts lunacy laws, 97, 105; "freedom cure for insanity," 239.
Chantemesse and Wisal. The persistence of the germs of tuberculosis in river water, 183.
Cheever, D. W. Shock, 293, 313.
Children. Experiment studies on some points concerning the causation and treatment of the summer diarrhœa of infants, Vaughan, V. C., 14; a study of the micro-organisms in the stomach and intestines in the summer diarrhœa of infants, Booker, W. D., 16; microscopic examination of the stomach and intestines in the summer diarrhœa of infants, Hoit, L. E., 16; practical hints about children, 44; a case of noma, Rotch, T. M., 35; inquiry into the influence of the temperature of the air on the death of infants from diarrhœal diseases; the bacteria of the alimentary canal, especially in the diarrhœas of infancy, Jeffries, J. A., 217; apparatus for the sterilization of infant food, Rotch, T. M., 286; lithotapaxy in male children, Keegan, D. F., 333; some post-hemiplegic disturbances of motion in children, Knapp, P. C., 495; case of infantile hemiplegia with marked spastic contracture and slight athetoid movements in the fingers, Smith, J. L., 509; report on diseases of children, Rotch, T. M., 573, 603; acute lobar pneumonia in children, Townsend, C. W., 631.
Children's Hospital. The new out-patient building of the Boston Children's Hospital, 392.
Chinese "nervelessness," 318.
Chismore, G. On the effects of rapid changes of altitude in an advanced case of interstitial nephritis, 335.
Cholagogues, 439.
Cholera. Pettenkofer and cholera, 44.
Circulatory System. Ectocardia cured by a plastic operation, Lanuelongue, 44; penetration of the heart by a slate pencil, Rotch, T. M., 63; hypertension of the arteries; therapeutic indications, 66, 91; report on progress in thoracic disease, Shattuck, F. C., 226; simultaneous ligature of the right carotid and subclavian arteries for aneurism of the innominate, Packard, J. H., 311; the arrest of hæmorrhage from wounds in the palm of the hand, Levis, R. J., 317; the cardiac changes in chronic Bright's disease, Loomis, A. L., 562; the treatment of valvular affections of the heart, DaCosta, 363; disturbances of the heart rhythm, with reference to their causation and their value in diagnosis, Baumgarten, G., 363; valves in the veins of the human intestines, Bryant, W. S., 400; the treatment of valvular diseases of the heart, 461; experience with strophanthus in heart disease, Devine, W., 479; sudden heart failure in diphtheria: its pathology and treatment, Smith, J. L., 480.
Clarke, M. D. Therapeutic nihilism, 199.
Classification. Classification of diseases, Baker, H. B., 559.
Classification of disease by means of comparative nosology, Allbut, C., 206.
Clothing. Woollen or cotton underclothing, 619.
Coe, H. C. Grouped cells in ascitic fluid as diagnostic of malignant disease of the peritoneum, 261.
Coley, W. B. Treatment of penetrating shot-wounds of the abdomen, 373.
Color-blindness. Description of a series of tests for the detection and determination of subnormal color-perception (color-blindness) designed for use in railway service, Oliver, C. A., 109.
Cold. The use of cold in diarrhœa of children during the hot weather, 164.
Colporrhaphy. New form of posterior colporrhaphy, Kellogg, J. H., 321.
Compression. Cases illustrating the use of compression, after the method of Mr. Gamgee, Burrell, H. L., 528.
Congress of American Physicians and Surgeons, 214.
Congress for the study of Tuberculosis, 182.
Connor, L. Report of standing committee on the requirements for preliminary education in the various medical colleges of the United States and Canada, 565.
Constipation. Postural treatment of constipation, Whitney, J. O., 25; postural treatment of constipation, 175.
Consumption. The treatment of consumption by residence at high altitudes, 488.
Corey. The therapeutic value of hypnotism, 484.
Cornil. On the transmission of tuberculous infection by the mucous membranes, 183.
Cornil and Toupet. On pseudo-tuberculosis in men and animals 184.
Corrosive Sublimate. The value of corrosive sublimate as a practical disinfectant, Hills, W. B., 169.
Councilman, W. T. Some further investigations on the malarial germ of Lavaran, 436.
Cream Pie. Food poisoning, Crocker, S. E., 230.
Creoline. Otis, D., 132.
Crime. The proper treatment of crime and criminals; ought the criminal to be dealt with as a lunatic? 338.
Crocker, S. E. Food poisoning, 230.
Croup. The comparative merits of tracheotomy and intubation in the treatment of croup, Gay, G. W., 311, 349.
Cushing, E. W. Changes in the uterine mucous membrane, 577.
Cushing, H. W. An improved method for the radical cure of femoral hernia, 546.
Cutaneous System. Report on progress in dermatology, Tilden, G. H., 6; a case of noma, Rotch, T. M., 35; two forms of skin tuberculosis, Baren, J. T., 151; address before American Dermatological Association, Atkinson, G. E., 335; the electrolytic decomposition of organic tissues, Rohe, G. H., 336; the value of salicylic acid in dermatology, Heitzmann, C., 336; kraurosis of the vulva, Heitzmann, C., 343; anthrarobin, Bronson, E. B., 337; personal observations on skin diseases in the negro, Morison, R. B., 338; the relations of papilloma to syphilis and tuberculosis of the skin, Morrow, P. A., 339; a report upon three cases of dermatitis herpetiformis, Graham, J. E., 339; dermatitis herpetiformis, with notes of three cases, Stelwagon, H. W., 340; molluscum contagiosum, Stelwagon, H. W., 341; note of a case of filaria medinensis, Van Heringen, A., 340; note relative to the condyloma from lesions induced by ingestion of some of the iodine compounds, Lyon, J. N., 340; the non-identity of lichen planus and lichen ruber, Fox, G. H., 342; the question of relationship between lichen ruber (Hebra) and lichen planus (Wilson), Robinson, A. B., 342; lichen ruber, as observed in America, and its differentiation from lichen planus, Taylor, R. W., 342; dermatitis tuberosa, Taylor, R. W., 343; dermatitis plantaris and palmaris, Bulkley, L. D., 343; recent progress in dermatology, Tilden, G. H., 500.
Cutler, E. G. Fæcal accumulation, 430, 434.
DaCosta. The treatment of valvular affections of the heart, 363; spasm of the bronchial tubes, 628.
Dana, C. L. The cortical localization of cutaneous sensations, 329.
Dandridge, N. P. Nerve stretching, 312.
Davenport, B. F. Report on food and drugs: their sophistication and analyses, 103; the detection of morphine in the urine as a means of diagnosis, 124.
Davenport, F. H. Report of progress in gynecology, 128; uterine displacements and their influence on the general nervous system, 172; some gynecological cases treated by the faradic current, 397, 405.
De Brun. Pulmonary tuberculosis in Styria, 183.
Delirium Tremens. The treatment of delirium tremens by strychnine, 510.
Dentistry. Progress in dentistry, Rollins, W. H., 59.
Dercum, F. X. A subcutaneous connective tissue dystrophy of the arms and back, associated with symptoms resembling myxœdema, 329.
Dermatology. Recent progress in dermatology, Tilden, G. H., 6., 500.
Dermoid cyst, Bolles, W. P., 605.
D'Espine. The bacillus of diphtheria, 514.
Deunne. Tuberculosis transmitted by the milk of a phthisical cow, 69.
Deutsch-medizinische-schrift-sucht, or the German Medical-Journal habit, Hawley, J. S., 166.
Devine, W. Experience with strophanthus in heart disease, 479.
Diabetes. Forms of diabetes mellitus, Seegen, 563.
Diagnosis. A matter of diagnosis, 259.
Diarrhœa. Experimental studies on some points concerning the causation and treatment of the summer diarrhœa of infants, Vaughan, V. C., 14; a study of the micro-organisms in the stomach and intestines in the summer diarrhœa of infants, Booker, W. D., 16; microscopic examination of the stomach and intestines in the

summer diarrhœa of infants, Holt, L. E., 16; treatment of chronic diarrhœa, 43; inquiry into the influence of the temperature of the air on the death of infants from diarrhœal diseases, Meinert, 73; the use of cold in diarrhœas of children during the hot weather, 164; the bacteria of the alimentary canal, especially in the diarrhœas of infancy, Jeffries, J. A., 217.

Digestive system. Experimental studies on some points concerning the causation and treatment of the summer diarrhœa of infants, Vaughan, V. C., 14; a study of the micro-organisms in the stomach and intestines in the summer diarrhœa of infants, Booker, W. D., 16; microscopic examination of the stomach and intestines in the summer diarrhœa of infants, Holt, L. E., 16; experimental researches relative to the action of medicaments on the biliary secretion and the elimination by this secretion, 20; postural treatment of constipation, Whitney, J. O., 23; visceral disease and insanity, 42; treatment of chronic diarrhœa, 43; progress in dentistry, Rollins, W. H., 59; inquiry into the influence of the temperature of the air on the death of infants from diarrhœal diseases, Meinert, 73; the surgical treatment of intestinal obstruction, 114; cases of laparotomy for tubercular peritonitis, Cabot, A. T., 121; clinical notes of a case of perityphlitis: laparotomy thirty-two hours after the beginning of the attack, Wyman, S. E., 126; the use of cold in diarrhœas of children during the hot weather, 164; foreign bodies in the rectum, Goodall, D. H., 166; postural treatment of constipation, Williams, E. T., 178; saccharine considered as an antiseptic of the digestic passages, 186; the bacteria of the alimentary canal, especially in the diarrhœas of infancy, Jeffries, J. A., 217; two cases of appendicitis, one fatal, Stedman, C. E., 241; a case of strangulated hernia, Beach, H. H. A., 242; peritonitis from perforating ulcer of the stomach, Fitz, R. H., 253; grouped cells in ascitic fluid as diagnostic of malignant disease of the peritonæum, 261; the medical relations of acute intestinal obstruction, Fitz, R. H., 295; the surgical treatment of acute intestinal obstruction, Senn, 295; the surgical treatment of typhlitis and perityphlitis, Ball, W. T., 309; the propriety of surgical interference in perforating typhoid ulcer, Mears, J. R., 310; a case of volvulus, Warren, J. C., 380; valves in the veins of the human intestines, Bryant, W. S., 400; a case of appendicitis, with autopsy, Warner, E., 404; acute yellow atrophy of the liver, Allen, C. J., 408; fæcal accumulation, Cutler, E. G., 430, 434; a case of ulcerative perforation of the transverse colon: laparotomy twelve hours later; death on the seventh day from septic peritonitis caused by fæcal extravasation, Richardson, M. H., 432, 435; concerning cholagogues, 439; on the treatment of intestinal occlusion by electricity, 439; the diagnosis and medical treatment of acute intestinal obstruction, Fitz, R. H., 445, 469, 493, 523; tubercular peritonitis, apparently cured by laparotomy, Morrill, F. G., and Bradford, E. H., 534; a case of appendicitis in a child, Whitman, R., 551, 553; movements of the stomach, 586; a case of intestinal obstruction, Richardson, M. H., 629, 633.

Diphtheria. The treatment of diphtheria, 369; its history, cause, and prevention, Hamilton, J. B., 411; sudden heart failure in diphtheria: its pathology and treatment, Smith, J. L., 480; the bacillus of diphtheria, D'Espine, 514.

Disinfection. Methods of disinfection as tested at the quarantine station below New Orleans, Kinyoun, J. J., 69; the value of corrosive sublimate as a practical disinfectant, Hills, W. B., 169.

Dislocation of hip of eleven months' standing: reduction by manipulation, Thorndike, W. H., 229.

Doctor at home, 438.

Doran, A. Ovariotomy in age, 118.

Doty, D. Description of Pullman, Ill., 586.

Draper, W. H. Address before Association of American Physicians, 359.

Drowning. A disputed case of accidental drowning, Winsor, F., 65.

Drugs. Report on food and drugs, Davenport, B. F., 103.

Dunsmore, G. Sepsis in obstetrics, 409.

Durant, C. E. Abortion, 232.

Duret. Glandular tuberculosis, 184.

Dwight, T. Demonstration of a model of frozen sections of the arm, with remarks on this method of teaching anatomy, 245, 285; recent progress in anatomy, 322.

Ear. A case of aural vertigo (Meniere's disease) relieved by excision of the membrana tympani and malleus, Barnett, C. H., 86; reflex influences in the production of nasopharyngeal catarrh, Buck, H., 87; hallucinations of hearing, Kite, J. A., 105; a contribution to the anatomy of the elephant's ear, Buck, A. H., 111; a case of polypoid angioma of the ear, Richards, H., 112; a case of false drum membrane, 112; the flexible catheter as a drainage-tube, with cases, 112; three cases of transient bilateral horizontal nystagmus in connection with purulent inflammation of the middle ear, Kipp, C. J., 113; an improved aural snare, Baisley, J. O., 113; othæmatoma or insane ear, Field, M. D., 583; a new form of clinical tuning fork, Blake, C. J., 604, 606; three casts of the membrana tympani, Morse, H. L., 605; treatment in cases where symptoms point to inflammation in the mastoid antrum and mastoid cells, Morse, H. L., 593, 606.

Edes, R. T. Dinner to foreign guests of the Congress of Physicians and Surgeons, 191; the relation of renal diseases to diseases of the nervous system, 328; the absolute and relative value of albumen and casts, and of renal inadequacy in the diagnosis and prognosis of diseases of the kidney, 361.

Editorials. Annual report of the Boston City Hospital for 1887, 18; history of a medicament, 19; experimental research relative to action of medicaments on the biliary secretion and the elimination by this secretion, 20; visceral disease and insanity, 42; treatment of chronic diarrhœa, 43; the Massachusetts Health Report, 66; hypertension of the arteries: therapeutic indications, i, 66; on the value of salt in the treatment of acute rheumatism, 67; the fourth year of the Harvard Medical School, 91; hyperte sion of the arteries: therapeutic indications, ii, 91; the surgical treatment of intestinal obstruction, 114; the mind-cure and faith-cure delusion, 116; leprosy in the Sandwich Islands, 117; sanitation sociologically considered, 138; an illustration of medical bulletins, 140; army medical examination, 140; the topography of the brain, 162; effect of ergot on the involution of the uterus, 163; the Yale Thermometric Bureau, 163; Gegenbauer on cænogenesis, 185; saccharine considered as an antiseptic of the digestive passages, 186; the scientific spirit of the age, 210; the breeding of papers and criminals, 211; density of population as a social and sanitary question, 233; yellow fever in Florida, 235; Servia's sanitary system, 257; the Association of Genito-urinary Surgeons, 258; a matter of diagnosis, 259; the first triennial congress of American physicians and surgeons, 288; yellow fever, South and North, 288; the German treatment of obesity, 290; the congress of American physicians and surgeons, 314; on the employment of inhalations in diseases of the bronchi and of the lungs, 344; shorthand as an aid to scientific study, 344; human beings as subjects of experimentation, 345; the index catalogue of the library of the Surgeon-General's office, number ix., 368; the treatment of diphtheria, 369; the President's pension vetoes, 390; on the treatment of hæmorrhages by revulsion over the hepatic region, 391; therapeutics as judged by figures, 413; intubation in Germany, 415; the doctor at home, 438; concerning cholagogues, 439; on the treatment of intestinal occlusion by electricity, 439; women and the study of medicine, 440; the treatment of valvular diseases of the heart, 461; the case of the late Emperor Frederick of Germany, 463; treatment of incontinence of urine by Rhus aromatica, 464; the mortality of pneumonia, 485; make way for liberty, 487; the treatment of consumption by residence at high altitudes, 488; on the diuretic action of strophanthus, 488; the treatment of delirium tremens by strychnine, 510; medical inspection of the Massachusetts Insane, 510; on special service, 511; improved provision for the insane at Providence, R. I., 511; the spread of tuberculosis, 512; the proper treatment of crime and criminals; ought the criminal to be dealt with as a lunatic? 538; puerperal fever a preventable disease, 539; pneumonia mortality in Massachusetts almshouses, 540; the registration of mortality and vital statistics, 561; Seegen on the forms of diabetes mellitus, 563; yellow fever on the cruiser Boston, 564; movements of the stomach, 586; secondary dementia, 587; a side light upon the plague of the sixteenth century, 612; gum chewing, 614; the death penalty by electricity, 615; annus medicus MDCCCLXXXVIII, 637; necrology of the Massachusetts Medical Society, 640.

Edson, C. The poison of typhoid fever, 609.

Education. The fourth year at the Harvard Medical School, 91; laboratories and museums of hygiene for teaching purposes, Proust, 94; the requirements for preliminary education in the various medical colleges of the United States and Canada, Connor, L., 505; the famous historic masters of the healing art were men of classical education, Fisher, G. J., 535; the necessity for post-graduation instruction in the present state of American medical education, Lee, C. C., 536; which is the liberal school? McIntire, C., 536; the influence of the work of the Illinois Medical Practice Act upon medical education, Johnson, H. A., 537.

Egan, P. R. Antipyrine as an analgesic, 466.

Electricity. Katalytic action of electricity; its practical value in rheumatic affections, Walton, G. L., 101; the curability of urethral stricture by electricity, Keyes, E. L., 332; the electrolytic decomposition of organic tissues, Rohé, G. H., 336; some gynecological cases treated by the faradic current, Davenport, F. H., 397, 405; on the treatment of intestinal occlusion by electricity, 439; the death penalty by electricity, 615.

Elephant. A contribution to the anatomy of the elephant's ear, Buck, A. H., 111.

Emerson, J. B. The flexible catheter as a drainage-tube, with cases 112.

Empyema. A new form for dressing in cases of empyema, Richardson, M. H., 388; permanent opening for empyema, Otis, E. O., 405.

Epilepsy. On a clinical report of cases of epilepsy following cerebral hemiplegia, Fisher, E. D., 327.

Eruptive Fevers. The arrest of secretions in the eruptive fevers, Brown, D., 509.

Ether. Observations of the time and amount of ether required to produce anæsthesia, Lovett, R. W., 549.

Eve, F. Eve on acinomycosis, 165.

Excisions. A contribution to the study of excisions of the larger joints, Ashhurst, J., Jr., 302.

Exophthalmic Goitre. One, possibly two, cases of Graves's disease, Bundy, F. E., 27, 36.

Eye. A contribution to the treatment of membranous opacities in the vitreous, Ball, C. S., 88; a case of pulsating exophthalmus cured by ligation of the common carotid artery, Buller, F., 88; pulsating exophthalmus, Kipp, C. J., 89; an analysis of 576 cases of the retraction of healthy human cornea examined with the ophthalmometer of Javal & Schiötz, Barnett, S. M., 89; œdema of the choroid and retina, Johnson, E., 90; symptomatic myopia, Mittendorf, W. F., 90; hysterical blindness in the male, with a report of three cases, Moore, W. O., 109; description of a series of tests for the detection and determination of sub-normal color perception (color blindness), designed for railway service, Oliver, C. A., 109; case of embolism of the central retinal artery, Oliver, C. A., 109; a case of double congenital iridiremia in a child whose mother exhibited a congenital coloboma of each iris, Theobald, S., 109; puncture of the retina for detachment, Sutphen, T. Y., 110; a case of glioma, Capron, E. P., 110; models exhibiting refraction by cylinders, Burnett, S. M., 111; designation of prisms by their refractive power, Jackson, E., 111; extraction of a partially absorbed cutaneous lens, Webster, D., 111; recent progress in ophthalmology, Standish, M., 152; ophthalmoplegia externa, Wadsworth, O. F., 207; recent progress in ophthalmology, Standish, M., 625; headaches and other nervous symptoms caused by functional anomalies of the eye, Oppenheimer, H. S., 634.

Fenwick, E. H. Notes upon the prognosis of organic stricture of the urethra, 332.

Fever. Continued and remittent fevers, 21.

Field, M. D. Othæmatoma or insane ear, 583.

Filaria. The history of the filaria sanguinis hominis, Mastin, W. M., 332; note of a case of filaria medinensis, Van Harlingen, A., 340.

Fisher, E. D. On a clinical report of cases of epilepsy following cerebral hemiplegia, 327.

Fisher, G. J. The famous historic masters of the healing art were men of classical education, 535.

Fiske, E. L. Antipyrine as an analgesic, 34.
Fisk, S. A. Antipyrine in sea-sickness, 238; spontaneous fracture of a rib, 325.
Fitz, R. H. Peritonitis from perforating ulcer of the stomach, 252; the medical relations of acute intestinal obstruction, 295; the diagnosis and medical treatment of acute intestinal obstruction, 445, 469, 493, 523.
Florida. Yellow fever in Florida, 235.
Fœtus. Can the fœtus in utero be infected by the mother? Wolff, M., 261; intra-uterine fœtal deformities, Blake, J. G., 498; a large baby, Lewis, E. R., 543.
Food. Report on food and drugs, Davenport, B. F., 103; food poisoning, Crocker, S. E., 230; apparatus for the sterilization of infant food, Roteh, T. M., 286.
Fox, G. H. The non-identity of Lichen planus and Lichen ruber, 342.

Museums. On medical museums, with special reference to the army medical museum at Washington, Billings, J. S., 265.
Naturalist. The physician as naturalist, Gairdner, W. T., 203.
Necrology of the Massachusetts Medical Society, 640.
Negro. Personal observations on skin diseases in the negro, Morrison, R. B., 338.
Nephrectomy. Willard, D. E. F., 312.
Nerve Stretching. Dandridge, N. P., 312.
Nervous System. On motor paralysis and other symptoms of poisoning from medicinal doses of arsenic, Putnam, J. J., 1, 10; a case of general paralysis of ten years' duration, death from heart disease, Jelly, G. F., 26; one, possibly two cases of Graves's disease, Bundy, F. E., 27, 36; a case of tetany, Jelly, 37; endemic cerebro-spinal meningitis, Townsend, C. W., 52, 63; a case of cerebro-spinal meningitis, Jacobs, H. B., 57, 63; two cases of cerebral meningitis, Jackson, H., 58, 63; a case of cerebro-spinal meningitis of the pneumonic type, with painful joints and worms, Mason, A. L., 62; a remedy for nervous headache, Wilmarth, J., 71; inveterate headache, with cases, Osgood, H., 76, 82; a case of athetosis, Pengra, C. F., 80, 81; peripheral paralysis following the use of the rubber tourniquet, Putnam, J. J., 107; three cases of transient bilateral horizontal nystagmus in connection with purulent inflammation of the middle ear, 131; two cases of cerebro-spinal meningitis, Sears, G. G., 131; nervous affections following injury: "concussion of spine," "railway spine," "railway brain," Knapp, P. C., 133, 326, 421, 449; abscess of the brain, Trumbull, J., 142; the topography of the brain, 162; uterine displacements, and their influence on the general nervous system, Davenport, F. H., 168; personal observations on multiple neuritis, Putnam, J. J., 185; cases of cerebral tumor, Webber, G. G., 277, 286; cerebral localization in its practical relations, Mills, C. K., 297; cerebral localization in its surgical relations, Park, R., 298; cerebral localization in its relation to aphasia, Starr, M. A., 301; three successful cases of cerebral surgery, Keen, W. W., 305; nerve stretching, Dandridge, N. P., 312; on nervous affections following injury "concussion of the spine," "railway spine," and "railway brain," Knapp, P. C., 326; heat centres in man, Ott, I., 326; on a clinical report of cases of epilepsy following cerebral hemiplegia, Fisher, E. D., 327; the relation of renal diseases to diseases of the nervous system, Edes, R. T., 328; the cortical localization of cutaneous sensations, Dana, C. L., 329; a subcutaneous connective tissue atrophy of the arms and back, associated with symptoms resembling myxœdema, Dercum, F. X., 329; subacute progressive polymyositis, Jacoby, G. W., 330; muscular dystrophies, Sachs, B., 330; hallucinations of hearing, Wingate, U. O. B., 359; the relation between trophic lesions and diseases of the nervous system, Seguin, E. C., 363; a case of focal epilepsy successfully treated by trephining and incision of the motor centre, Lloyd, J. H., 365; infectious neuritis, Putnam, J. J., 366; a typical case of disseminated sclerosis, with a post-mortem showing only leptomeningitis cerebri, Gray, L. C., 366; aneurism of an anomalous artery, causing antero-posterior division of the optic chiasm and bitemporal hemianopsia, Mitchell, S. W., 367; a contribution to the study of muscular tremor, Peterson, F., 367; hereditary chorea, Sinn, C. W., 368; hysteria, Brynton, H., 411; neurasthenia: its differentiation and treatment, Gray, L. C., 458; report of a case of tremor treated by hypnotic suggestion, Birdsall, W. A., 484; six cases of treatment with animal magnetism, Mason, O., 484; nervous affections following injury, Knapp, P. C., 490; some post-hemiplegic disturbances of motion in children, Knapp, P. C., 495; neurosis of the bladder, Blake, J. G., 505; case of infantile hemiplegia, with marked spastic contracture and slight athetoid movements in the fingers, Smith, J. L., 509; muscular dystrophies, Sachs, B., 581; massage in writer's cramp and allied affections, Graham, D., 569, 609; observations on the steadiness of the hand and on static equilibrium, Bullard, W. N., 595; subdural abscess of the brain, Stokes, W., 618; headaches and other nervous symptoms caused by functional anomalies of the eye, Oppenheimer, H. S., 634.
Neurasthenia, its differentiation and treatment, Gray, L. C., 458.
Neuritis. Personal observations on multiple neuritis, Putnam, J. J., 253; infectious neuritis, Putnam, J. J., 366.
Nihilism. Therapeutic nihilism, Clarke, M. D., 199.
Nocard. The dangers arising from the use of meat and milk from tuberculous animals, 183.
Noeggerath, E. The harmlessness of cerebral laceration, 94.
Noma. A case of noma, Rotch, T. M., 35.

Nordman. Statistics and treatment of placenta prævia, 165.
Nurse. The nurse at large, Osgood, H., 618.
Nursing. A system of free nursing as organized in Philadelphia, Price, J., 346.
Oberlander. The diagnosis and treatment of chronic arthritis, with demonstrations of instruments, 331.
Obesity. The German treatment of obesity, 290.
Obstetrics. The importance of practical obstetrics in the course of instruction given by medical schools, Parsons, T., 506.
Old families, Lagneau, G., 490.
Oliver, C. A. Description of a series of tests for the detection and determination of subnormal color-perception (color blindness), designed for use in railway service, 109; case of embolism of the central retinal artery, 109.
Opium-habit. The causes and prevention of the opium-habit and kindred affections, Wilson, J. C., 505.
Oppenheimer, H. S. Headaches and other nervous symptoms can-ed by functional anomalies of the eye, 634.
Orthopraxy. A method of determining the angle of flexion of the diseased leg in hip-disease, Kingsley, G. L., 6; two cases of incision into the hip-joint, with observations as to "distraction" in hip-disease, Bradford, E. H., 147, 155; a contribution to the study of excisions of the larger joints, Ashhurst, J., Jr., 302; recent progress in orthopedic surgery, Bradford, E. H., and Lovett, R. W., 475.
Osgood, H. Inveterate headache with cases, 76, 82; the nurse at large, 618.
Osler, W. Puerperal anæmia and its treatment with arsenic, 454.
Otis, E. O. Creoline, 132; photoxyline, 132; permanent opening for empyema, 405.
Otis, F. N. Demonstration of a perfected evacuator and an improvement in the method of removal of debris from the bladder, 333; résumé of an experience of seventeen years with the operation of dilating urethrotomy, 335.
Ott, I. Heat-centres in man, 327.
Ovarian cyst. Beach, H. H. A., 253.
Ovariotomy. Ovariotomy and marriage, Tait, L., 45; ovariotomy and age, Doran, A., 118; résumé of two and one half years' experience in abdominal surgery, Irish, J. C., 621.
Packard, J. H. Supra-pubic cystotomy, 308; simultaneous ligature of the right carotid and subclavian arteries for aneurism of the innominate, 311.
Palmer, E. E. Retrojections in gonorrhœa, 331.
Papilloma. The relations of papilloma to syphilis and tuberculosis of the skin, Morrow, P. A., 339.
Paralysis. A case of general paralysis of ten years' duration: death from heart disease, Jelly, 25.
Parasites. The history of the filaria sanguinis hominis, Mastin, W. M., 332; note of a case of filaria medinensis, Van Harlingen, A., 340.
Paris. Paris letter, 466.
Park, R. Cerebral localization in its surgical relations, 298; pyæmia as a direct result of gonorrhœa, 331.
Parsons, T. The importance of practical obstetrics in the course of instruction given by medical schools, 506.
Pathology. Address on pathology, Aitken, W., 206.
Paul, C. Saccharine considered as an antiseptic of the digestive passages, 186.
Paupers. The breeding of paupers and criminals, 211.
Peculiar People. Make way for liberty! 487.
Pengra, C. P. A case of athetosis, 80, 81.
Pensions. The President's pension vetoes, 390.
Perineal Section. Five cases of perineal section, with exceptional complications, Porter, C. B., 148, 156.
Perityphlitis. Clinical notes of a case of perityphlitis: laparotomy twenty-eight hours after the beginning of the attack, Wyman, S. E., 126.
Peterson, F. A contribution to the study of muscular tremor, 367.
Pettenkofer and Cholera, 44.
Pharynx. The anatomy, physiology, and therapeutics of the pharynx, Bailey, A. C., 410.
Photoxyline. Otis, E. O., 132.
Physical Culture. Report of physical culture in schools, Adam, Z. B., Bradford, E. H., and Withington, C. F., 179.
Physiology as she is taught in the public schools, 394.
Placenta Prævia. Statistics and treatment of placenta prævia, Nordman, 165.
Plague. A side light upon the plague of the sixteenth century, 612.
Pneumonia. The mortality of pneumonia, 485; pneumonia mortality in Massachusetts almshouses, 540.
Poisons. On motor paralysis and other symptoms of poisoning from medicinal doses of arsenic, Putnam, J. J., 1, 10; arsenic poisoning through the maternal milk, Brouardel, 70; unusual susceptibility to sedative remedies, Blodgett, A. N., 201; food poisoning, Crocker, S. E., 230; current toxicological notions, 418; some historical and statistical facts concerning the use of arsenic as a poison, Cabot, S. W., 435.
Population. Density of population as a social and sanitary question, 233.
Porro's operation. A case of Porro's operation, performed on account of multiple myomata, saving both mother and child, Mixter, S. J., 455.
Porter, C. B. Five cases of perineal section, with exceptional complications, 148, 156; pelvic hæmatocele, 624.
Pregnancy, affections connected with. Early rupture of a tubal gestation sac: operation, Zuctrér, J., 22; a case of labor with threatening symptoms, Reynolds, E., 30, 34; report on obstetrics, Green, C. M., 31; a case of purulent puerperal peritonitis successfully treated by incision and drainage, Woodward, S. B., 33; affections connected with a case of hydatiform mole, Smattuck, G. B., 358; di-cussion on puerperal septicæmia, 405; sepsis in obstetrics, Dunsmore, G., 409; puerperal anæmia and its treatment with arsenic, Osler, W., 454; a case of Porro's operation, performed on account of multiple myomata saving both mother and child, Mixter, S. J., 455; a case of pregnancy in the left half of a double monster, 489; puerperal fever a preventable disease, 539; an unusually rare case of uterine births, Brennan, 541; induction of premature labor, Bayet, 542; effect of ergot on the involution of the uterus, 163; statistics and treatment of placenta prævia, Nordman, 165; report of cases confined at the Boston Lying-in Hospital, Boardman, W. E., 196, 202; abortion, Durant, C. E., 232; pregnancy and operative surgery, Tiffany, L. McL., 312; two cases of laparotomy for extra-uterine pregnancy, Richardson, M. H., 549, 551.
Prescription, how to construct a, 590.
Price, J. A system of free nursing as organized in Philadelphia, 346.
Prize offered to medical microscopists, 620.
Prous. Laboratories at the museums of hygiene for teaching purposes, 94.
Puerperal Fever a preventable disease, 539.
Pullman, Ill. Doty, D., 586.
Putnam, J. J. On motor paralysis and other symptoms of poisoning from medicinal doses of arsenic, 1, 10; peripheral paralysis following the use of the rubber tourniquet, 107; personal observations on multiple neuritis, 253; infectious neuritis, 366.
Pyæmia as a direct result of gonorrhœa, Park, R., 331.
Quarantine. A new quarantine act, 141; quarantine stations of the Atlantic coast, 559.
Rafin. Lactic acid in tuberculous ulcerations and lupus, 417.
Railway Injuries. Nervous affections following railway injuries, Knapp, P. C., 133; on nervous affections following injury ("concussion of the spine," "railway spine," and "railway brain"), Knapp, P. C., 133, 326, 421, 449.
Rauch, J. H. The wear and tear of the medical profession, 45; yellow fever panics and useless quarantines, its limitation by temperature, 559.
Recent Progress. Dermatology, Tilden, G. H., 6; obstetrics, Green, C. M., 31; dentistry, Rollins, W. H., 59; food and drugs, Davenport, B. F., 103; gynecology, Davenport, F. H., 126; ophthalmology, Standish, M., 152; thoracic disease, Shattuck, F. C., 226; surgery, Burrell, H. L., and Cushing, H. W., 246, 283; anatomy, Dwight, T., 322; therapeutics, Williams, F. H., and Delano, S., 354, 381; orthopedic surgery, Bradford, E. H., and Lovett, R. W., 475; dermatology, Tilden, G. H., 500; diseases of children, Rotch, T. M., 573; diseases of children, Rotch, T. M., 603; ophthalmology, Standish, M., 625.
Rectum. Foreign bodies in the rectum, Goodsall, D. H., 166.
Redard. Surgical intervention in tuberculous osteo-arthritis of the tibio-tarsal joints and of the feet in children, 184.
Reed & Carnrick's soluble food, 318.
Respiratory System. On thoracic deformity produced by adenoid growths in upper pharynx, Loewenberg, B., 46; reflex influences in the production of naso-pharyngeal catarrh, Buck, A. H., 87; report on progress in thoracic disease, Shattuck, F. C., 226; iodoform in hæmoptysis, 238; the comparative merits of tracheotomy and intubation in the treatment of croup, Gay, G. W., 311, 349; on the employment of inhalations in diseases of the bronchi and of the lungs, 344; permanent opening for empyema, Otis, E. O., 405; intubation in Germany, 415; the mortality of pneumonia, 485; the treatment of consumption by residence at high altitudes, 488; pneumonia mortality in Massachusetts almshouses, 540; spasm of the bronchial tubes, DaCosta, J. M., 628; acute lobar pneumonia in children, Townsend, C. W., 631.
Reynolds, E. A case of labor with threatening symptoms, 30, 34.
Rheumatism. Cascara sagrada in rheumatism, Goodwin, H. T., 22; on the value of salol in the treatment of acute rheumatism, 67; katalysation of electricity: its practical value in rheumatic affections, Walton, G. L., 101.
Rib. Spontaneous fracture of a rib, Fisk, S. A., 325.
Richards, H. A case of polypoid angioma of the ear, 112; a case of false drum membrane, 112.
Richardson, M. H. Case of supra-pubic cystotomy for tumor in the bladder, 158; observations on the surgical treatment of malignant growths, 193, 223; a new form for dressing in cases of empyema, 388; a case of ulcerative perforation of the transverse colon: laparotomy twelve hours later; death on the seventh day from septic peritonitis caused by fæcal extravasation, 432, 435; two cases of laparotomy for extra-uterine pregnancy, 549, 551; a case of intestinal obstruction, 629, 633.
Robinson, A. B. The question of relationship between lichen ruber (Hebra) and lichen planus (Wilson), 342.
Rockwell, F. W. Case of removal of both testicles for recurrent carcinoma, 332; case of nephro-lithiasis, complicated with hydronephrosis, in which lumbar nephrotomy was performed, 333.

ON MOTOR PARALYSIS AND OTHER SYMPTOMS OF POISONING FROM MEDICINAL DOSES OF ARSENIC.[1]

BY JAMES J. PUTNAM, M. D.

THE figures for a portion of the Faradic reactions are as follows: —

Thenar em. right,	115 mm.
Thenar em. left,	105 mm.
Hypothenar em. right,	115 mm.
Hypothenar em. left,	105 mm.
Exten. com. dig.	90 mm.
Exten. carpi. rad.	100 mm.
Deltoid (contractions excessively feeble),	100 mm.
Biceps (contractions also excessively feeble).	100 to 120 mm.

The examination with the galvanic current gives for the deltoid and biceps K Cl.C. at 2.5 to 3 m. a., with the small electrode placed upon the motor point; for the exten. com. dig. about 4 m. a. (K Cl.C greater than An Cl.C). There is no reaction of degeneration anywhere.

To sum up, therefore, we have here a patient, past middle life, attacked with widespread muscular paresis, attended by moderate atrophy, affecting mainly the muscles which move the extremities on the trunk, but also, to some extent, those of the distal portions of the limbs; rapidly progressive for five months, then retrogressive; characterized by moderate diminution of electrical irritability to both currents, and by increased mechanical irritability; preceded and accompanied by severe rheumatoid pains about the joints, but without other marked disorders of the sensory system; and associated with symptoms of considerable and persistent drowsiness, and general depression of the nervous energy; and we find also the urine containing an unmistakeable trace of arsenic, which must have come, so far as is known, either from the wall-paper during October and November, or from the therapeutic doses of Fowler's solution which had been taken five months before.

It should also be stated that the patient has of late, during his recovery, been using for his asthma, a secret remedy, which has been found on analysis to contain arsenic, together with an iodine preparation probably hydriodic acid, and other substances, and that under this treatment he has done well. In estimating the importance of this fact, it should be remembered that we are now dealing, presumably, not with a case of arsenic poisoning, but with a neuritis which the arsenic left behind it, and that for neuritis, arsenic in the proper dose is of admitted value.

The danger of poisoning is only present when the dose is too large, or the elimination, including the metabolic processes by which the tissues react to the poison, is slow or imperfect.

At the present time the arsenic (the exact dose of which is unknown), is being passed off rapidly, as a recent examination of the urine has demonstrated. Possibly the presence in the mixture of potassic iodide and other diuretic substances, is hastening the elimination.

Fortunately, the favorable turn of the disease renders it now almost unnecessary for us, in deciding upon the diagnosis, to eliminate progressive muscular atrophy and the other myopathies of spinal origin; and the absence of sensory symptoms other than pain, practically excludes diffuse myelitis.

There remain, as possible diagnoses, acute multiple neuritis and acute primary myositis, different forms of which have been described by Wagner,[8] Henry Jackson,[9] and other observers to whom these writers refer. Acute myositis is a rare affection, and is usually rapidly fatal, or runs a progressive course. It is ushered in by rheumatoid pains, usually following exposure to cold and wet, or severe muscular strain. The attack is usually attended by fever, often by swelling of the muscles and œdema of the skin. The distribution of the symptoms varies, but it is more common in this disease than in neuritis, to see the larger muscles principally affected. Only a few cases of this clinical type, and ending in recovery, have been reported, and there is some doubt whether part of these were not cases of neuritis.

The case reported to-night seems to me to belong with this obscure class. The evidence in favor of the arsenical origin has been materially weakened, as stated above, by the discovery of arsenic in the wall-paper. Nevertheless, for the sake of calling attention to this possibility, I allow what I had written to stand unchanged.

The principal causes of neuritis, leaving out the traumatic forms, are exposure to cold and wet, certain infectious diseases, alcohol, lead, arsenic, and a few other poisons which need not be considered here. Finally, some cases are of unknown origin, and, very rarely, even in Northern climates, a case is met with that seems referable with some probability to specific infectious influences. Of these causes, the first four can be set aside as out of the question or improbable. The symptoms came on in the pleasant season of June and no exposure had preceded them. We cannot, however, positively exclude the causes of unknown character, nor specific infection. The question remains: What degree of probability is to be attached to the diagnosis of poisoning from arsenic?

The clinical picture presented by this case differs in several respects from the group of symptoms usually met with in arsenical poisoning from large single doses, but it should be remembered that we probably have to deal here, not with a typical, but with a modified or abortive form of the disease, such as occurs from the long-continued action of the poison taken in very small quantities. These forms vary widely, but they present similar features, such as neuralgic pains, drowsiness, loss of strength and energy, and sometimes serious paralyses.[10]

It has been pointed out above that the distribution of the muscular paralyses from arsenic poisoning is usually such that the muscles moving the hands and feet are the most affected, but, also, that it is not very uuusual to find the larger muscles of the trunk and limbs more or less weakened. The distribution met with in the present case, where the larger muscles are the ones most severely affected, is not noted as marking a special type of arsenical neuritis, but we find, at least, cases in which the larger muscles are involved equally with the smaller.[11] In certain cases of paralysis from

[11] Comp. Gourbeyre; Gazette Méd. 1858. Obs. xxiv; Gerhardt: Sitzungsber. der Phys. Med. Gesellschaft zu Würzburg, 1882, p. 98: Jaeschke; Inaugural Dissertation, Breslau. Case 1.

lead-poisoning, the deltoids are very prone to suffer, and they may even be attacked before the other muscles, as in a case which I have recently had the opportunity of observing. Possibly a wider acquaintance with cases of arsenical paralysis will show us that similar differences in type are to be found also among them.

The very fact that such widely different agents as lead, arsenic, alcohol, sulphide of carbon, and the poison of the tubercular, and other bacteria, induce, on the whole, such similar types of neuritis, suggests that there is a common factor at work which is independent of the particular agent, and must consist in some peculiarity of the affected tissues. If this is so, then a variation in the symptoms which is often met with in one of these forms of poisoning, such as that from lead, will be likely to occur to a greater or less extent in the rest, when the conditions are favorable.

In a case of acute, fatal, infectious neuritis, which I have recently observed with Dr. M. A. Morris, of Charlestown, the left deltoid was the first muscle to be attacked with severe paralysis.

A second set of facts, pointing in the same direction has recently been brought forward by Chittenden, in a paper read before the Medico-Legal Society of New York on June 11, 1884,[12] where it was shown that lead, arsenic and similar poisons do not always accumulate in the same organ of the body, as the liver or the kidneys, but that the position of greater accumulation varies according to the rapidity of absorption (solubility) of the special preparation ingested, the rapidity of elimination, and similar factors. Thus, in some instances, the brain, or the muscles, and even special groups of muscles, contain a relatively large amount of the poison, and although, to be sure, it is mainly in cases of acute poisoning, where death occurred before the arsenic had had time to distribute itself evenly, that this irregularity of distribution occurs, yet the author admits (reprint, p. 26) that our information as to the cause of these facts is not yet sufficiently exact. These peculiarities in the local accumulation of the poisonous agent must certainly affect the symptoms, even if it be true that it is the degree of vulnerability of the special tissues, and not the amount of poison present, that chiefly determines whether or not paralysis will result.

As regards the bearing of the fact that paræsthesia and anæsthesia were wanting, in the case which I have reported, upon the diagnosis of neuritis from arsenical poisoning, it is to be borne in mind that this fact militates no more strongly against the diagnosis of neuritis from arsenic, than against the other forms of neuritis. It is certain, as a matter of clinical observation, that these symptoms are sometimes wanting in each one of the forms of toxic neuritis, notably those from lead, as well as in some cases of local neuritis. It is also certain that in such cases severe and persistent rheumatoid pains may be present in the neighborhood of the joints,[13] and it is equally true that the nutrition of the muscles may be seriously impaired, even in arsenical cases, without tenderness or marked or persistent numbness being present; as, for example, in a case reported by Jaeschke (l. c.).

Finally, the important question remains to be answered, whether it is possible that such serious symptoms as those described could be induced by such small quantities of arsenic as five drops of Fowler's solution taken three times daily for six weeks. Such a result as this is, doubtless, rare, but an examination of the cases given below will show that it is possible. When it does occur the question naturally arises whether an unusual susceptibility on the part of the patient, or an unusually slow elimination, leading to accumulation of the poison in the tissues, is the cause.

Most writers say that arsenic does not accumulate, but is rapidly eliminated. By this is, of course, meant that the accumulation does not go beyond a certain limit, for it is evident that a drug which is not wholly eliminated until from one to six weeks after being taken, as is the case with arsenic, must, for a certain time, have been absorbed faster than it could be eliminated.

Moreover, certain writers believe that arsenic really is stored up in the body. Rayer[14] quotes Bardeley to this effect, and Taylor cites Mr. Hunt, a writer on skin diseases, as holding the same view, but says that, in his own opinion, the facts adduced to show accumulation really show defective elimination, due to some particular cause, such as impaired action of the kidneys.

In the case under discussion to-night the kidneys seemed to be healthy, but the urine constantly contained a considerable amount of crystals of oxalate of lime, on repeated examinations during October and November. It is also to be remembered that the patient had been for a long time asthmatic, and was subject to chronic bronchitis, so that the process of oxidation may have been impaired.

It is also very important, in investigating the question of size of dose, to remember that it makes a vast difference in the result what preparation of arsenic has been taken, and that the common practice of expressing all doses in terms of the arsenious acid contained in them is clinically objectionable. Thus, as Devergie long ago pointed out[15] ten minims of Fowler's solution contains only one-tenth grains of arsenious acid, but is, in its poisoning action, equivalent to several times that quantity. The same writer expresses the opinion, though without stating his evidence, that the sodium arseniate, as found in Pear on's solution is relatively less active than the potassium arseniate of Fowler's solution. Devergie cites Boudin as having given up to 0.15 (two and one-half grains) of arsenious acid in intermittent fever; whereas, Fowler himself gave only from one to thirty minims (gr. one-third) of his solution and occasionally with more or less serious results.

Under the general heading of *unusual susceptibility*, the fact should be considered, that whereas most persons taking small and repeated doses of arsenic for a long time become habituated and indifferent to its presence, in others this indifference is not established, or else ceases after a time, so much so that there is a general feeling that it is unsafe to continue the use of arsenic as a medicine too long.

But have we any gauge of the length of time that it may be given with safety in a given case? So far as I know, there is none, and an examination of the cases cited below will show that the interval which may elapse before symptoms of chronic poisoning show themselves varies widely.

[13] Medico-Legal Journal.
[12] See Stillé, Materia Medica, Art. Arsenic.

[14] Dict. de Med. et de Chir. Prat.
[15] Bull. Gén. Therap., lxxii, p. 49.

The peasants of Steiermark learn, by gradual habituation, to take up to two or three, possibly four, grains a day, without the least inconvenience, a dose which is beyond the border line of danger, but it is stated by several writers that they become occasionally the victims of paralysis and other serious symptoms as a result of this habit.

I have recently seen a patient with rheumatic arthritis who has used $\frac{1}{30}$ gr. of arsenious acid three times daily, with regular intermissions, for a year or more without discomfort. This winter, she found that even a few doses caused abdominal pain and swelling of the eyelids.

Possibly, the occasional bad results may sometimes be due to a temporarily impaired secreting power on the part of the kidney, induced by the arsenic, which is known to cause, at times, albuminuria.

Taking the reports as we find them, we learn such facts as the following about the occasional effects of small and moderate doses:

(1) Gourberye[16] treated a female patient for a cutaneous affection with gtt. ij of Fowler's solution (presumably 3 t. d.) for fifteen days, but violent rheumatoid pains came on, which obliged her to keep her bed, and ceased when the medicine was suspended. The same thing happened again the following year, under the same circumstances.

(2) Huss[17] saw convulsions, pains in the back, and generalized muscular weakness and tremor, and formication follow the use of arsenious acid in dose of gr. $\frac{1}{14}$, 2 t. d.

(3) Gaillard[18] reports the case of a woman who was advised to take fifteen drops of Fowler's solution twice a day for two weeks; then three times a day for two weeks; then four times a day for the same period. The treatment was continued up to the fifth week, in spite of some unpleasant effects. Then a whole train of poisonous symptoms appeared, ending in paresis of all four extremities, which continued to grow worse for some weeks after the medicine had been given up. In the five weeks, she may have taken upwards of two ounces and a half.

(4) Dr. Turnstile,[19] of Bath, Eng., reports the case of a young woman who took ♏ iij of liquor arsenicalis for seven days, at the end of which time she became for a time seriously prostated. Also,

(5) A similar condition in a young man.

(6) In the *Canada Medical and Surgical Journal*, Montreal (1886–87, Vol. 15, p. 716), a case is reported where Fowler's solution, in doses of ♏ xx to xxx caused acute symptoms of poisoning, with paresis, ending in death. At the autopsy, signs of active multiple neuritis were found, with lesser changes in the spinal cord.

(7) Dr. Cummings[20] reports the case of a man who took gtt. iij to vi of Fowler's solution three times daily for two months; then a smaller dose for another month. This produced what was called "irritation of the lower extremities and symptoms of inflammation of the stomach."

(8) Dr. Jno. Barry[21] reports the case of a lady, who, while taking a course of arsenic (dose not given) under the observation of a London practitioner of great experience with the drug, was suddenly attacked with paralysis of both hands and feet. There is, however, some reason to think, to judge by the report, that an external use of arsenic may have played a part in the result.

(9) Dr. Hastings[22] reports the history of a patient who, after taking gtt. iij to v of Fowler's solution for some weeks, suffered from great weakness and partial paralysis of both arms and legs, with burning pains in the feet.

(10) Gibb[23] gives the history of a woman who for years had used arsenic as a medicine. She was finally attacked (November 18th) with severe neuralgic pains, successively in both groins, and the left hip, shoulder, and side, and a few months later with a numbness, and eventually complete paralysis of the legs, which are said, by the way, to have "felt quite numb, although sensibility (to objective tests?) was perfect."

The patient died on April 23d of the following year, and, on examination of the tissues, a trace of arsenic was found in the bones and liver. This is an important observation, because, if we may assume that she ceased taking arsenic at the time the severe neuralgic symptoms set in, we find that elimination was not complete at the end of six months.

(11) In the *Dublin Quarterly Journal*, Vol. 36, p. 474, the case is recorded of a man who took ♏ iij of Fowler's solution three times daily for ten or twelve months, at the end of which time symptoms of arsenic poisoning came on suddenly, terminating in death at the end of thirty-six hours. If Taylor's[24] opinion is to be taken, this would prove that a dose sufficient to cause poisoning must have been recently taken, but the history gives no hint that this occurred.

(12) Another instance of poisoning from medicinal doses is recorded by Dr. C. L. Dana in *Brain*, 1887, and forms one of his interesting cases of pseudo-tabes, with paralysis. The patient had been taking Fowler's solution in gradually increasing doses, and had finally reached f ʒss[25] (whether more than once daily is not stated), when the paralytic symptoms came on.

(13) Dr. Hooper[26] reports the following case, which is of special interest:

The patient, an adult male, took five drops of Fowler's solution three times daily, from the month of October until the 24th of June of the following year. At that time he came to Dr. Hooper for an ophthalmia, and by his advice the arsenic was immediately discontinued. Nevertheless, the following symptoms soon made their appearance: headache, drowsiness, nausea, excessive sense of weakness and prostration, rapid pulse, progressive paralysis, widespread muscular tremor, conjunctivitis with œdema, insomnia, irritation of the larynx and trachea, and increasing debility, ending finally in death on the 13th of September, three months after the cessation of the arsenical treatment.

(14) Dr. Jones[27] gives the case of a lady, who, for a cutaneous disease, was given gtt. v to xv of liquor arsenicalis, 3 t. d. After taking these doses for about a month, she was found presenting the symptoms of

intense gastro-intestinal irritation, scanty urine, serious trophic changes in the legs, associated with crampy sensations and "partial loss of motion and sensation."

If, instead of confining ourselves to the paralytic cases, we should ask how often general symptoms of poisoning result from small doses of arsenic, it would be an easy matter to extend this list.

Thus, to go no further than Taylor, a careful and apparently conservative writer, we find in his "Treatise on Poisons" (2d Am. ed., p. 339), the following cases cited:

(15) Dr. Burne. A young female took gr. $\frac{1}{60}$ of assenious acid [= about ♏ vi of Fowler's solution] daily for four days. She then suffered from inflammation of the stomach, delirium, palsied shaking of the head, and such a degree of debility and exhaustion as to place her in imminent danger.

(16) Taylor (p. 340). Gr. $\frac{1}{30}$, taken once or twice a day for seven days, apparently caused "sickness, irritation of the skin, and eczema over the whole body."

(17) Taylor (p. 395). An adult female took in three doses ♏ xxx of liquor arsenici chloridi (said to be a very poisonous preparation) in the course of twenty-four hours. The quantity of arsenic thus taken was not more than the tenth part of a grain, and yet the symptoms which followed were of a severe kind, resembling those of chronic poisoning. There was constriction of the throat, pain and irritation of the stomach and bowels, tingling and numbness of the hands and feet, loss of muscular power, and a feeling of extreme depression. The medicine was withdrawn, and the patient slowly recovered. Taylor gives the usual medicinal dose of this preparation as from three to ten minims.

Finally, I would suggest that some of the lighter symptoms of poisoning from arsenic in small doses may be overlooked or referred to other causes.

I have recently had in my own practice the following case: I ordered for an adult female, with Graves's disease, the following mixture:

R	Fowler's sol.	6.00
	Pyrophosphate of iron	5.00
	Elix. calisaya	500.00
M.		
Dose, two teaspoonfuls, t. i. d.		

Within, literally, a day or two after beginning to take it, the patient felt symptoms of severe gastro-intestinal irritation, from which she had never suffered before — great pain, nausea, vomiting, and for a time diarrhœa. The medicine was discontinued, but it was a month before she was able to retain solid food, and during the convalescence, as she expressed it, "the whole skin of her mouth came off."

These instances of serious poisoning from small doses of arsenic are, no doubt, very rare, as compared with the vast mass of cases where the drug has been given for long periods without harm. Still, probably more such cases exist than have been reported, and, at any rate, there are enough to show that the danger of poisoning from medicinal doses, though slight, yet is real, and I cannot but sympathize with the following sentiment, expressed by Jaeschke in his inaugural dissertation: "Arsenic is at once a dangerous and a treacherous poison. Let the limits of safety once be overstepped, and there is risk, not only that serious temporary results may follow, but also that, after these have passed away, painful and disabling affections may be left behind."

That it is an agent of the greatest value is also true, and we need to study its action with great care, in order to extract its good effects and avoid its dangers. To this end I think the following facts should be borne in mind:

(1) The temporary tolerance of a given dose of arsenic, whether large or small, is not a sufficient proof that it is being disposed of so that it will not cause symptoms of poisoning after an indeterminate time.

(2) It is not always enough to withdraw the medicine when the first symptoms of poisoning show themselves, partly because several weeks at least may still elapse before the remaining arsenic can be wholly eliminated, and partly because the symptoms are apt to go on increasing in severity without renewed ingestion.

When this paper was read, Dr. F. C. Shattuck reported in connection with it a very interesting case, which will be found described in the records of the meeting. The patient was a young married lady, and her symptoms consisted in rheumatoid pains in all four limbs, of long duration, and accompanied with some general debility, and with tenderness in the muscular masses and along some of the nerve-trunks. Arsenic had been found in the wall-paper, and an analysis just made by Professor Wood had shown the presence of a small quantity also in the urine. This case acquires a special interest from the fact that the lady is niece to my patient, and that both of them belong to a family in which marked ability and grave neuroses have been common. I had purposely avoided dwelling, in my paper, on the possible influence of a neuropathic constitution in predisposing to an organic nervous affection such as this, feeling that my diagnosis ought to be based on more definite clinical grounds. That such a predisposition may exist is, however, almost beyond a question, and I gladly take the opportunity offered by Dr. Shattuck's interesting communication, to call attention to the fact.

A CASE OF TUBERCULOSIS OF THE BLADDER, PROSTATE AND KIDNEYS, ORIGINATING IN TUBERCULOUS EPIDIDYMITIS.—AUTOPSY.[1]

BY F. S. WATSON, M.D.

THE specimens I show here to-night come from a patient aged thirty-five years, who died to-day, and who has been under my observation for the past fourteen months.

I offer the history of the case to the Society somewhat in detail, as serving to illustrate the course of a disease which is often obscure and difficult of diagnosis.

V. M., aged thirty-three years, married eight years since. Consulted me February 10, 1887. Twelve years previous he had his first gonorrhœa, a gleet persisting for three years afterward. A fresh attack occurred soon after recovery, which only lasted a few weeks. About eight years ago noticed a small nodule in either epididymis, about the size of a pea. These nodules were hard and painless, and, I may say at once, never changed their character during the patient's life. Four years ago he began to suffer from frequent urination.

Coincident with the appearance of frequent urination the stream grew smaller.

These symptoms remained unchanged during the next two and a-half years, when he sought surgical ad-

[1] Read before the Suffolk District Medical Society, at the Annual Meeting, April 28, 1888.

vice. The diagnosis of stricture was made, and the patient was operated upon by the method of divulsion. The previous symptoms were at once aggravated. The operation was followed by chills and fever, and he lost in a few weeks thirty pounds weight. On recovery from the acute attack, however, a No. 16 English steel sound could be passed readily into the bladder.

Eight months before I saw him he had measles, and on recovery noticed that his urine contained a dirty gray sediment and small clots of blood from time to time. Two months later he entered the Massachusetts General Hospital, where he was treated by the introduction of large sounds, 32 (French), and washing of the bladder with boracic acid solutions. The symptoms were aggravated by whatever local treatment was employed. When I first saw him he had been out of the hospital for two months. He was thin and haggard, had an anxious expression of countenance, was very weak, and walked bent over, and feebly. The desire to urinate was almost constant, and every fifteen minutes the bladder voided an ounce or a few drops of urine, thick with pus. The urine was neutral. (Specific gravity, 1005.) Contained a large trace of albumen. The sediment consisted of pus corpuscles, blood corpuscles, epithelial cells of a great variety of shapes. He complained of a con stant dull pain in the perineum. The prostate, by rectal examination was slightly enlarged. There was no tenderness on pressure over the pubes.

Microscopic examination of the urine for tubercle bacilli was negative.

During the next month internal medication for the relief of the painful cystitis failed to give the least relief. Blood in small quantities appeared in the urine occasionally, independent of exertion.

He was then sent to the City Hospital, where, owing to the kindness of Dr. E. H. Bradford, in whose service he entered, I made a digital exploration of the bladder through the perineum.

The inner surface of the bladder was roughened, as though occupied by very superficial ulcerations. Beyond this the examination was negative.

The operation was not followed by any constitutional disturbance, nor, on the other hand, was any mitigation of the symptoms obtained by it. The patient made a rapid recovery, and the perineal wound was healed at the end of three weeks. He left the hospital, however, in an exceedingly poor condition. The nodules in each epididymis, the marked constitutional disturbance of the patient, wasting and loss of strength, the unvarying presence of pus, and the occasional appearance of blood, the aggravation of the symptoms on every local interference, the total inefficacy of local and medicinal remedies in mitigating the symptoms, and the feeling of the mucous membrane of the bladder led me to the conclusion that I was dealing with a case of tuberculous disease of the genito-urinary tract. The patient was now put upon cod-liver oil, nourishing food, and sent to the country. I did not see him again for three months, when he walked strongly into my office, told me that he had gained thirty pounds in weight, and could hold his water for an hour at a time without difficulty. He then returned to the city. Shortly afterward, that is, about six months before his death, the amelioration in his symptoms ceased, and they returned in their full severity, pain being now a prominent symptom, referred chiefly to rectum and perineum. Rectal examination now showed a greatly enlarged prostate. Defecation became exceedingly painful. About one month later the rectal symptoms suddenly disappeared, and rectal examination showed a prostate of normal size, the inference from these facts being that the prostate had been the seat of a tuberculous abscess, which had finally ruptured into the urethra, causing a disappearance of the swelling. The specimens confirm, as you will see, this view.

The patient now gained again, and a surprising degree of strength and energy returned. Two months later, however, a new accession of bladder pain, with great prostration, supervened, and to-day, after as suffering an illness as I have ever watched, he died.

No clinical evidence of tuberculous disease of parts of the body other than of the genito-urinary tract existed during life. A partial autopsy only was possible. The kidneys, bladder, prostate, membranous, urethra, rectum and testicles were obtained.

In the epididymis of this testicle I have laid open the nodule which was the earliest manifestation of the disease, and apparently its point of origin. It consists of a sac, with a cheesy contents entirely broken down, a process of long standing. Both lobes of the prostate are occupied by the now somewhat shrunken cavities of tuberculous abscesses, containing cheesy material, and communicating by several openings into the prostatic urethra, some of which would admit a No. 12 French bougie.

The whole organ, however, was not enlarged. The bladder-wall was irregularly thickened, the capacity of the viscus small, the mouths of the ureters stood open, and were of a size to admit a goose quill. The mucous membrane was occupied throughout its entire extent by superficial ulcerations. Both kidneys are the seat of a tuberculous pyelo nephritis, the pyramids and cortical portions being occupied by cavities in various stages of development. The case throws no new light of importance on the class of disease of which it is an example, but emphasizes several facts already dwelt on by various writers, amongst which may again be pointed out as assisting in the diagnosis, the slow development of the symptoms, marked remissions in their severity, which are apt to arouse false hopes of the patient's recovery, and prove very deceptive, the constant presence of large quantities of pus of a dirty grayish-white color, the occasional appearance of blood, generally in small clots or mixed with shreds of pus, without exciting cause. The pus in this case was unlike that seen in cases of ordinary cystitis, in that it lacked the mucous and the ropy consistency so often noted in cases of ordinary cystitis of so severe a grade. The alkaline decomposition and foul smell were but slight. The presence of the nodules in either epididymis independent of gonorrhœal process. The evident seriousness of the lesion in a previously strong, healthy man, as shown by the great loss of flesh and strength. The aggravation of the symptoms by all local interference. The total inefficacy of internal medication. The improvement following removal to better hygienic surroundings, and the employment of cod-liver oil and good food. Tubercle bacilli would no doubt have been found had the urine been more frequently examined for them.

The case furnishes another example of the local limitation of the disease in some instances to the genito-urinary tract.

Two of the questions I asked myself while the patient was under my care, were: Was there a time when surgical interference might have prevented the general eruption of the disease along the genito-urinary tract? There was an interval of several months after the appearance of the nodules in the epididymes before urinary symptoms came on. An excision of these nodules might have prevented further progress, and should always, I think, be urged at an early period, when they cannot be definitely traced to a venereal or traumatic source. The second question is: Could any operation have been performed for the relief of the patient's sufferings after the disease was well established?

In another case which presented such suffering as this patient had, I should certainly advise the suprapubic opening of the bladder and the stretching of the vesical neck, in the hope of affording relief to pain. The perineal opening which I made in this patient did not relieve pain. It is interesting in this connection to note two cases of Professor Guyon's, published in the *Revue de Chirurgie*, April 10, 1888, page 314, in which he recommends that the high cut be performed in cases where the disease be limited to the bladder only, with a view to radical cure. It will be doubted by some if the disease ever occurs in this limited form.

His first case was that of a young man of twenty-four years. Cystitis for eighteen months, great pain, tubercle bacilli in the urine. Supra-pubic opening of the bladder, and swabbing out of the bladder with saturated iodoform oil, drainage. The tubes were removed on the seventeenth day. Forty-five days later pain was greatly diminished. Two years and a-half later patient was in excellent health, and the urine was clear, free from pus and bacilli.

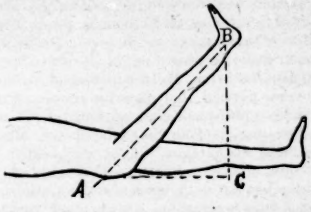
Second case. Man of forty years. Vesical pain for four months. Numerous bacilli. Palliative treatment for four months. Had no effect. Operation as before. Curretted the inner surface of the bladder, and touched it with cautery. Tubes removed on the fifteenth day. Bacilli disappeared six months later. This patient, however, has still a cystitis.

A METHOD OF DETERMINING THE ANGLE OF FLEXION OF THE DISEASED LEG IN HIP DISEASE.

BY GEORGE L. KINGSLEY, A.B., HARVARD MEDICAL SCHOOL.

THE estimation of the amount of flexion of the leg upon the pelvis, in the acute stage of hip-disease, is of much importance as a matter of record and as an indication of the progress of the case. The estimation of this angle is commonly made by the use of the goniometer. As one seldom has this instrument at hand, and as its use is attended with many disadvantages, the following method is offered:

The object of this article is to furnish a ready and accurate method of estimating with a common tape-measure the angle of flexion of the leg, and is intended to be supplementary to the article by Dr. Lovett,[1] on the estimation of adduction and abduction by a similar method. Lay the patient on his back on a table or any flat surface, and then raise the diseased leg by the heel until the lumbar vertebræ touch the table; this shows that the pelvis is in the normal position and the angle which the leg makes with the table, the angle



C A B, is the angle of flexion of the thigh, from the normal position. It is this angle which it is desired to measure. Having placed the child in this position, measure off two feet on the external aspect of the leg with a tape measure with the zero of the tape on the table at (A), and note the point (B), from here measure the perpendicular distance in inches to the table (C), consult Table I and opposite the number of inches found by measuring B C, will be found the number of degrees representing the flexion of the diseased leg from the normal position.

Now we have a right-angled triangle A B C, of which the sides A B (24 inches) and B C (by measurement) are known. $\frac{BC}{AB}$ = sine B A C (the angle of flexion), or B C = A B sine B A C. Therefore, if we compute by this formula a table which shall give the angles corresponding to the various lengths of B C, having measured this perpendicular distance (B C) we can by glancing down the table until we find the number corresponding to the distance measured, ascertain the number of degrees in the desired angle.

TABLE I.

In.	*Deg.*	*In.*	*Deg.*	*In.*	*Deg.*	*In.*	*Deg.*
.5	1	6.5	16	12.5	31	18.5	50
1.0	2	7.0	17	13.0	33	19.0	52
1.5	3	7.5	19	13.5	34	19.5	54
2.0	4	8.0	20	14.0	36	20.0	56
2.5	6	8.5	21	14.5	37	20.5	58
3.0	7	9.0	22	15.0	39	21.0	60
3.5	9	9.5	24	15.5	40	21.5	63
4.0	10	10.0	25	16.0	42	22.0	67
4.5	11	10.5	27	16.5	43	22.5	70
5.0	12	11.0	28	17.0	45	23.0	75
5.5	14	11.5	29	17.5	47	23.5	80
6.0	15	12.0	30	18.0	48	24.0	90

If the leg is so short that it is impracticable to measure off twenty-four inches we can measure to a point on the leg distant twelve inches from the table, ascertain the distance to the table in a perpendicular line just as before, double this distance and look in the table as before.

REPORT ON PROGRESS IN DERMATOLOGY.

BY G. H. TILDEN, M.D.,
Physician to City Hospital, Department of Diseases of the Skin: Instructor in the Boston Polyclinic.

TREATMENT OF LUPUS ERYTHEMATOSUS.[1]

THE treatment of this disease being an uncertain and often thankless task, the following lecture upon the subject by an eminent authority is of interest. The treatment of lupus erythematosus is essentially different both in ways and means, from that of lupus vulgaris. In the case of lupus vulgaris it is possible by chemical or mechanical means to destroy and get rid of the pathological infiltration which constitutes the disease. When this has been done and the loss of

[1] Kaposi. Allgemein. Wiener Med. Zeitung, No. 8, 1888.

tissue thus occasioned, has been replaced by healthy granulation tissue, then something definite has been accomplished. It is beyond our power to prevent the occurrence of new nodules of infiltration, but those which exist can be entirely removed, the difficulties in the way consisting in the localization, distribution and amount of pathological tissue which may be present. With regard to lupus erythematosus the affair is in certain respects more difficult, in others more promising than is the case in lupus vulgaris. In lupus erythematosus we have to deal with an inflammatory process, which is peculiar in the fact that the inflammatory infiltration eventually undergoes a change which is probably fatty metamorphosis, and from its absorption there results an atrophy and shrinking of the cutaneous tissue. This inflammatory process is not confined to the sebaceous glands and their neighborhood (as suggested by the name seborrhœa congestiva), but may occur anywhere in the skin where there are bloodvessels, and if the disease has advanced to the stage of atrophy of tissue, it is impossible to remedy the defect which has taken place.

The primary object in the treatment of lupus erythematosus is to induce in some way a cessation of the inflammatory process before fatty degeneration and atrophy of tissue have occurred. If this result be obtained then the disease disappears without leaving behind any trace of its existence. Such an arrest and disappearance of inflammatory infiltration can in no case be induced by the use of caustics, but it may and does occur without any treatment whatever, and in the worst instance, lupus erythematosus if left to itself, never results in the formation of ulcers and deep-seated cicatrization such as are met with in lupus vulgaris. It is all important, therefore, in the treatment of lupus erythematosus never to employ means which will do more damage than the disease itself will occasion. The outlook, however, is unsatisfactory, inasmuch as it is impossible in any given case to state beforehand what sort of treatment is going to produce a good result or whether the treatment employed may not by reason of the irritation it causes, induce an extension of the disease, which otherwise might not have taken place. It is this uncertainty of result and prognosis which renders the treatment of lupus erythematosus so eminently unsatisfactory, and in no instance is it possible to give any definite opinion as to how long the disease will last or as to the result of treatment.

The corollary of all this is that treatment should always be begun with the application of remedies which are mild in their action. Often more will be accomplished in this way than by the use of more active measures. The first thing to be tried is rubbing the diseased regions of skin with various kinds of soap, toilet soap, soda and potash soaps, soft soap and spiritus saponatus kalinus. The soap should be applied to the skin with energetic friction every day, and it is noticeable that the spots of lupus erythematosus do not readily become excoriated. Often the healthy skin in the neighborhood will be deprived of epidermis much sooner than a spot of lupus erythematosus. This is the case whether soap, or other and more active remedies are employed, and is due to the fact that one of the essential features of the disease is, that the sebaceous glands involved, produce a thick, overlying layer of accumulated and fatty epidermis, which is more resistent to the action of soap or caustics than is normal epidermis. After a spot of lupus erythematosus has been rubbed with strong soap, there oozes from the lesion a small amount of serum which should be allowed to dry, forming a small yellowish crust which falls off in four or five days. If, after this, the edge of the inflammatory patch remains flat and does not extend peripherically, it signifies that the treatment has been beneficial. If signs of irritation appear, the border of the infiltrated patch becoming elevated and the redness increasing in extent as well as in degree, then indifferent and soothing substances should be applied until the inflammatory exacerbation subsides. In the same way may be used in various strengths caustic potash and pure ammonia water, also mild acid applications of acetic, muriatic or carbolic acids. The strong acids, especially mineral acids, such as sulphuric, nitric and chromic acids should never be used. Whenever the stronger applications have been used and have effected nothing, one should go back again to the milder remedies, for what is inefficient at one time may be beneficial at another. Tar, in combination with various soaps, such as sulphur and napthol soap, or in the ointment known as Wilkinson's ointment, sometimes produces good results. Occasionally applications of ice, lead water or of liquor Burowi are beneficial, and of the regular caustics the best are pyrogallic acid, salicylic acid, chloride of zinc and arsenic paste. Brilliant results are sometimes seen from the application of mercurial plaster. In cases where the disease is extensive the best treatment consists in the use of tar and mercurial plaster, applied to small regions of the disease at a time. Patients with lupus erythematosus have a certain tendency towards anæmia and phthisis, and in most cases, good diet and pure air, are needful, together with arsenic, iron and cod-liver oil.

PATHOLOGY OF LICHEN RUBER.[2]

Since the year 1880 the writer has collected fifty-two cases of lichen ruber, of which number thirty-five occurred in men and seventeen in women. Seven of these cases exhibited also lichen affecting the mucous membrane of the mouth and tongue. In only two instances did the disease take the form of universal lichen ruber acuminatus, and this variety of the malady was found to be much more intractable to treatment by the administration of arsenic both by the mouth and by subcutaneous injection, than lichen planus. The mixed form occasionally met with was not found to be especially obstinate as regards treatment, however.

The possibility of a neuropathic origin of lichen ruber was first suggested to Köbner by the case of a woman forty-five years of age, who was affected simultaneously with widespread lichen ruber acuminatus and with the early symptoms of progressive bulbar paralysis. In this instance the skin of the whole body was red, the color of a raspberry, and the woman was covered from head to foot with elevations of the skin, rough, like a file, between which there existed islands of normal skin, which appeared as depressions of the general surface. Besides the paralytic symptoms, the patient suffered from intolerable itching, and presented a high degree of emaciation.

In another instance the localization of the cutaneous eruption followed closely the distribution of certain

[2] Köbner. Berliner Klin. Wochenschrift, 1888, No. 20. Centralblatt für die Med. Wissenschaften, 1888, No. 8.

cutaneous nerves, and in the same case a recurrence of the eruption was confined in its distribution to exactly one side of the penis. As further evidence of the neurotic origin of lichen ruber, Köbner mentions the intense itching which deprives the patients of sleep, and which may long precede, as well as accompany the cutaneous eruption. The majority of patients, also, who suffer from this malady, are of the neurotic type, and the affection often follows mental shock, worry and anxiety. It is worthy of notice, also, in this connection, that in many cases the outbreak of lichen was preceded by attacks of urticaria, which in one instance outlasted the lichen by one year and a half. In many instances the patients exhibited a sensitive condition of the vaso-motor system, which manifested itself by the ready formation of the so-called "taches cérébrales" upon irritation of the skin. Occasionally, also, the eruption seemed to be produced by scratching, or by the irritation due to the pressure of some article of clothing. Contrary to Lassar's experience, no connection could be made out between the occurrence of the disease and the occupation of the patient, and in no instance could any form of micro-organism be detected in microscopic preparations made from the cutaneous nodules peculiar to the disease.

A FORM OF CHRONIC INFLAMMATION OF THE LIPS AND MOUTH, WHICH SOMETIMES ENDS FATALLY AND IS USUALLY ATTENDED BY DISEASE OF THE SKIN AND NAILS.[3]

The author's attention has been drawn during the past ten years to certain cases of a peculiar variety of disease, in which a severe form of ulcerative stomatitis was followed by disease of the skin, and which sometimes, after a duration of several months, ended fatally. These cases are important by reason of their severity, from their close resemblance, in some instances to syphilis, and from the fact that they are curable, for the most part, by one remedy only. On this latter point the author speaks with caution, because the evidence with regard to it is not complete. There appears, however, reason for believing that small doses of opium, frequently repeated, will usually cure the malady, which resists all other drugs, and tends slowly but surely to end in death. The author is not prepared to offer any suggestions as to the pathogenesis of this disease, but merely describes its clinical features. In all of the best marked examples of the affection seen by Hutchinson, the patients have been men, generally past middle life, living in the country, enjoying until the beginning of the attack, excellent health, and in positions which enabled them to secure all the comforts of life. In some less well marked cases the patients were residents of London. The writer considers it not improbable that the pathological condition of the system which gives rise to this form of stomatitis may be allied with that which is at the root of certain forms of skin disease, notably pemphigus, in which the constitutional symptoms are severe, and in which the mouth is occasionally affected. In pemphigus, however, the cutaneous manifestations always precede the affection of the mouth, whereas, in the form of disease under consideration the reverse is the case.

The first instance of the malady seen by the author occurred in a master currier of fifty-eight years of age, who began to be ill during the end of December, 1879, and died in about four months. His illness commenced with soreness of the mouth, which was quickly followed by swollen hands and feet "like chilblains." Later on a vesicular eruption appeared on his hand, with inflammation of the nails, and there was spontaneous ptyalism with sore throat and lips. Then a bullous eruption extended over the whole body, and the nails fell off. Lastly large masses of granulation tissue developed on the excoriated surfaces left by the bullæ and some of these masses became pedunculated. The man died from exhaustion, and the autopsy showed some recent broncho-pneumonia with pleurisy, on the left side, and also the existence of a large lympho-sarcomatous tumor situated in front of the spine, and embedding the pancreas and large vessels. The existence of this tumor was not suspected during life, and the writer is inclined to regard it merely as an accidental concomitant of the disease. The next case occurred in a gentleman whose age is not given, and began with a "very severe form of inflammation of the mucous membrane of the mouth, the whole interior of the mouth being intensely reddened, and exhibiting on the arch of the palate, on the tonsils and pharynx, patches of very delicate pellicular whiteness, which looked as if they had been produced by the application of caustic." In a few weeks there was developed ptyalism which became constant, then appeared in the flexures of the joints, moist and warty growths, followed by suppurating inflammation of the nails, and by the development of a pemphigoid eruption over the whole body. After the illness had lasted five months the patient, who had become emaciated and weak, died from exhaustion. The post-mortem examination revealed no structural disease except recent hepatization of the lower lobe of the right lung. These two are the only fatal cases of the disease which have come under the author's own care, and in neither of them did treatment, principally by arsenic and quinine internally, have any effect whatever. In the second case, opium was given, but not until the very last stages of the malady. Two other cases, in which the stomatitis was severe, but in which the cutaneous symptoms never became formidable, have been also seen by Hutchinson. They both occurred in males, forty-six and fifty years of age respectively. They began with superficial ulcerations of the mucous membrane of the mouth, the margins of which were reddened, and the bases of which were covered by a distinct pellicle of a grayish color, the removal of which caused bleeding. In one case, after the affection of the mouth had lasted some three months, there appeared some patches of a sort of papillary psoriasis on the backs of the hands, his toenails became inflamed, and several of them were lost. In the other instance there was no affection of the skin except a lichenoid eczema of the left side of the abdomen, which had existed for some years. In both cases there was much weakness and loss of flesh, and in neither did the treatment by arsenic, quinine, iodide of potassium, the use of various mouth washes, and the application of caustics to the ulcers, have any effect whatever. Both cases recovered permanently under the use of small and often-repeated doses of opium. Another and very similar case, occurring in a farmer, sixty-six years of age, and who became very weak and much emaciated, recovered permanently un-

[3] Jonathan Hutchinson. Medico-Chir. Transactions, Vol. lxx, p. 421.

der the administration of opium for several months. A sixth instance of the malady, the patient being under the care of another physician, was also seen by Hutchinson, but the treatment by opium was not resorted to until a late period in the disease, and the patient died. In this last case the affection of the mouth was coincident with an eruption of the skin, the exact nature of which is not stated.

These six cases are regarded by the writer as examples of the severer form of the disease. In three instances death resulted. In two the patient is known to have recovered under the opium treatment, and, to have remained well. All the patients were men, and none of them were under forty-five years of age. All had been in good health until the first symptoms of soreness of the mouth occurred. In all the three fatal cases, the inflammation of the skin which followed the affection of the mouth was extensive and severe, while in the three which recovered it was but slight, in two, indeed, being almost absent. In one of these three, although the eruption was but very limited in extent, affecting only the hands and feet, there was the peculiar feature of inflammation of the toenails, and from four of the toes the nails were shed. In none of the fatal cases had the opiate treatment been tried until within a very short period of death.

In the next group of similar, but less severe cases, the author mentions instances in which are still encountered the combination of sore mouth and an eruption on the skin, the soreness of the mouth taking precedence in point of time over the skin disease. In these cases, however, the disease showed itself much more amenable to treatment, and, indeed, the patients occasionally recovered without any definite treatment. The disease also showed a tendency to recurrence after a few years' interval. One of the patients in this group was a woman thirty-five years of age, and the other two were men, aged, respectively, thirty-six and forty-six years. In one of these, arsenic effected a definite, but temporary, cure on more than one occasion. In two of them the beneficial effect of opium was very marked, in one a rapid cure taking place under its influence. In none of these three cases was there any approach to the failure of health which took place in the cases included in the first group. The patients in this group being younger than the others, suggests to the writer that the age of the patient may have something to do with determining the severity of the affection. The cutaneous eruptions in these cases were of various kinds, in one instance consisting of dry and scaly superficial patches on the body, combined subsequently, with an abundant eruption of erythema multiforme upon the hands; in another, of patches of erythema upon the hands and feet, which vesicated, but without producing bullæ. In all of these the affection of the mouth consisted in an acute stomatitis, attended with the formation of superficial excoriated patches, which were covered with a whitish, pellicular membrane, the removal of which caused bleeding.

In conclusion, the author remarks that none of these cases seem to throw any light upon the real cause of the disease. It may, however, be conjectured that it is allied to some of the severe forms of skin disease which are attended by failure of the general health, and which tend to a fatal issue. Examples of this are seen in pemphigus, of which the natural termination is death in six months, unless cured by arsenic, and in which, as a further feature of resemblance, the mouth is in some cases affected, as well as the skin. Nor is pemphigus the only instance, for pityriasis rubra and certain rare forms of psoriasis and lichen ruber and planus, especially when occurring in the aged, show a tendency to end in death by exhaustion. The precise form of the skin eruption does not seem to be of much consequence, for whatever it is, if it become very extensive, the patient's strength may fail and death result. It is a very remarkable fact that these diseases, like the one described, almost always begin in those who, up to the time of the attack, have been in excellent health. The failure of health always appears to be due to the extension of the local disease. The features in which the cases described differ from those just referred to, is that the mouth became inflamed before the skin was affected, and suffered throughout with preponderating severity. The disease of the skin differed much in the several cases. In one it appeared to be a direct extension from the lips to the skin of the chin, which became greatly thickened and covered with papillary outgrowths. In others there was developed a bullous eruption, resembling pemphigus in appearance. In several instances, warty excresences occurred in great abundance in the flexures of the joints, while in two instances a few eczematous patches on the hands and abdomen constituted all the skin affection that ever showed itself. In all the severe cases the nails became inflamed. It is impossible not to be struck with the apparently specific efficacy of opium and the uselessness of other drugs. The writer thinks it may be fairly asserted that in all the cases where opium was given early enough, it cured the patient, not only removing the local symptoms, but restoring perfect health, and he does not doubt but that this observation of the usefulness of opium may with advantage be extended to many chronic maladies affecting the skin in elderly persons.

A striking example of the beneficial effect of opium in this direction is given by Hutchinson at the close of the article. The patient was a woman sixty-one years of age, who had been in good health until her hands began to inflame. The disease took on the form of a sort of exfoliative dermatitis, which developed with exact symmetry on hands and feet, and gradually spread. All the nails were inflamed, and when the process invaded the scalp all the hair fell out. No treatment had any effect in arresting the progress of the malady. She was treated by Hutchinson for four months with arsenic, phosphorus, and other remedies internally, and various local applications, but with no better result. Things kept growing worse and worse, and her general health became visibly affected, the patient being bald, emaciated, and with hands and feet rendered quite useless by the malady. Opium was then prescribed. Improvement began immediately, and after about four months' continual use of this remedy the patient was in excellent health, her hands were quite well, and all her hair and nails had grown again. At the time the paper was read the opium had been laid aside for three months, and there was no recurrence of the malady, but subsequently there appeared some slight symptoms of a relapse.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

H. L. BURRELL, M.D., SECRETARY.

ANNUAL meeting, Saturday evening, April 28th, at 19 Boylston Place, 8 P. M., DR. JOHN HOMANS, President, in the Chair.

Records of the previous meeting read and approved.

A list of the deaths and removals was then read.

The Secretary read a communication relative to the establishment of a hospital for the treatment of inebriates.

There was then read a communication from the Georgia Medical Society, in reference to the furnishing of medical and surgical supplies free of duty.

On motion of DR. J. J. PUTNAM, the matter was referred to a Committee, and the President referred it to the Committee on Supervision.

Dr. J. J. Putnam read the paper of the evening, on

DISEASE CAUSED BY MEDICINAL DOSES OF ARSENIC, WITH REMARKS ON THE DIAGNOSIS OF MULTIPLE NEURITIS.[1]

DR. C. F. FOLSOM said: I do not know that I have anything to add to the paper. I have been extremely interested in it, and certainly can second everything that Dr. Putnam has said in regard to the diagnosis of multiple neuritis. If I recollect correctly, the first case that I recognized as such was in 1881. It was then an extremely uncommon disease. There had been very few cases in the wards of the City Hospital, and scarcely any cases reported as such in the outpatient department. At the present time it is a very frequent disease, or else we are very often making the diagnosis where it does not belong. I think that it is undoubtedly frequent, but it is quite possible that we may be swinging the pendulum a little too far in that direction. A great many cases, as Dr. Putnam says, are obscure and difficult of diagnosis because the usual symptoms do not occur. In many cases, also, the etiology is extremely difficult, so that it seems to me, before settling on any one factor, especially an unusual factor, one should be extremely careful to exclude all other possible causes.

I remember a case, for instance, which Dr. Lyman was kind enough to send me some time ago, a thoroughly well-marked case of multiple neuritis, in which it was for some time quite difficult to get at the cause, but it finally appeared that the lady had had two small children with diphtheria, and that she had been present in the sick-room for a great part of the time. She did not know that she had diphtheria at that time, but, considering the peculiar character of the multiple neuritis, I have no doubt that it was post-diphtheritic. In the same way, we have cases which are diagnosed as locomotor ataxia, in which, if you give iodide of potassium, the symptoms disappear; that is to say the case was one of multiple neuritis of syphilitic origin.

Sometimes, for instance, patients deny syphilis, and you learn from the physician who has seen them before that they had some signs of syphilis, and got well under syphilitic treatment. I don't say this to throw doubt upon the diagnosis in this case, but to make prominent the necessity of being very careful to exclude all possible sources of error in diagnosis. The question arises in this case whether the multiple neuritis, granting the diagnosis, of course, is due to arsenic given in the prescribed quantity, namely, five minims, t. i. d., so long ago and for so short a time. If so, I should stop prescribing arsenic altogether, valuable as I consider it. In this case, it seems to me, there is doubt whether the arsenic given is the real cause of the disease, if, as I understand, the gentleman improved while taking an asthma remedy containing arsenic.

DR. PUTNAM: He was not taking that at that time.

DR. FOLSOM: Even then, there are a great many other sources of arsenic. I recall a patient who has been under my care for between two and three years; that is to say, I am the only person who has prescribed for her during that time. During this past winter she had evident symptoms of arsenic-poisoning. Dr. Hasket Derby was kind enough to see her in consultation with me. We have never found the source of the arsenic. There was no question whatever what it was, and the lady got quite well by leaving the suite of rooms in which she was living. There was no question of its being arsenic-poisoning. There was no arsenic in the wall-papers, but we did not examine everything in the suite, carpets, etc. That case illustrates the difficulty of making a diagnosis, and in my mind it would throw doubt on the diagnosis of multiple neuritis from arsenic given in medicinal doses, unless all other sources of arsenic are excluded. It is one which, of course, would be followed with a good deal of interest. I have seen something like ten cases of arsenical neuritis reported in the medical journals in the last three or four years, most of them from large poisonous doses; a few of them were from smaller quantities taken into the system over a very considerable period of time. The fact that, in the case reported this evening, arsenic was found in the urine five months after it was given up as a prescription, I should think would throw doubt on its origin.

DR. P. C. KNAPP said that he had listened with great interest to Dr. Putnam's paper, for he had under his care at the present time a case of mild arsenical paralysis from poisoning from wall-paper. He could add nothing to Dr. Putnam's account of paralysis from medicinal doses of arsenic; certainly, as Dr. Folsom said, five minims three times a day for six weeks was a remarkably small dose to produce neuritis. He had never given very large doses of arsenic, rarely exceeding eight minims of Fowler's solution, and in those doses he had never seen paralysis, although he had, of course, seen the ordinary symptoms of gastro-intestinal irritation and swelling of the eyes.

DR. F. C. SHATTUCK spoke of a patient now under his care and suffering from an unquestionable neuritis, thus far at least, of only moderate intensity. This patient is a young married lady, a niece of Dr. Putnam's patient, and has this winter been much shut up in the house. The neuritic symptoms first appeared about three weeks ago, and consist in constant dull pain in the arms and legs, with stiffness of the joints, particularly the knees, and well-marked tenderness on pressure, not only over the main nerve trunks of the extremities, but also over the muscles themselves. A week ago samples of wall paper were sent Professor Wood, who found the paper of the library, the room in which, next to her bedroom, the lady passes most time, to contain a dangerous amount of arsenic. A sample of urine was then sent, and Professor Wood

[1] See Vol. cxviii, p. 646, of the Journal.

has been so kind as to hasten the analysis that its result might be reported this evening. He finds a trace of arsenic in the urine. Have we here the cause of the neuritis? There is no other apparent causative agent operative in the case. The near relationship between the two patients is of interest, and suggests the question whether there is any constitutional sensitiveness to the metal common to them both. We are everyday struck by the remarkable difference between individuals in the toleration of, or resistance to, toxic influences of various kinds.

This difference in resisting power is shown, perhaps as well as by anything else, by the wide differences in the toleration of alcohol. Can we not explain in a similar way the fact — for Dr. Putnam certainly seems to give us grounds for holding it to be a fact — that in certain persons a comparatively small amount of arsenic produces marked changes in the peripheral nerves?

Dr. Webber said: I have been very much interested in Dr. Putnam's paper, and think he has brought up a subject which it is well for us to keep in mind, that there is a possibility of persons being poisoned with arsenic when it is given in medicinal doses long continued. Whether six weeks is long enough to be poisoned I think is very doubtful, but I have had patients sent to me, children with chorea, who had been taking small doses of arsenic for what seemed to me an unreasonable length of time, much longer than seemed to me was safe; taking doses which were entirely insufficient to relieve the disease — three or four drops of Fowler's solution — instead of running the dose up to as much as the patient will bear. Dr. Putnam has mentioned one case from a journal in Canada where twenty or thirty drops were given. That seems to me a large dose, and could hardly be called a moderate or small dose. The fact that the pains are about the joints, and that the joints are chiefly affected, might lead to the question whether or not the muscles which are affected are not affected secondarily to the disturbance of the joint, as Charcot has shown that the joint affections are followed by a disturbance in the nutrition of the muscles; and in some of the cases where the electrical reaction is not very much disturbed, whether it may not be secondary to the pain in the joints, and not due to the direct disturbance through the nerves.

It is interesting to notice, as Dr. Folsom has mentioned, how neuritis has come forward prominently, and so many different causes giving rise to it, and the variety in the symptoms. It seems to me it is a subject still requiring investigation how these various remedies affect the nerves, what portion of the nerve structure is affected. It is a subject open to experimental investigation, I think, and might lead to important results. The neuritis from lead, from alcohol, from arsenic and sulphide of carbon, and other causes, the neuritis which follows disease, such as the various fevers. It would, I think, lead possibly to very important results if we could have that investigation.

I think that Dr. Putnam, in closing his paper, has made some very important statements as to the caution and care necessary in using arsenic, in the fact that arsenic may be cumulative. That we should bear in mind that if it is not eliminated, there is a chance for such an explosion as he has mentioned.

Dr. Bullard: I would like to ask Dr. Putnam one question, and that is whether every other possible source of the arsenic was examined in this case, and whether it was simply supposed to have been the medicine.

Dr. Putnam: I cannot say whether it might not have been so. The only thing there could have been suggested was the wall-paper and the carpets, and this was a house where he had lived many years. Still, that inquiry ought, of course, to be made.

Dr. Buckingham: I would like to ask the question whether, when the multiple neuritis follows, we are to have any warning before the explosion occurs; any warning to enable us to stop the arsenic.

Dr. Putnam: I only want to say a few words. It seems to me that I entirely agree with Dr. Folsom that it is unadvisable to make extraordinarily apparent the consequences of a familiar process unless they can be well proved. At the same time, I think it is fair, at least, to inquire from time to time whether there are a number of facts that come together and support a rather unfamiliar fact; and that is what I attempted to do here. Of course, we all know that we give five drops of arsenic, and many people are capable of taking more than that, not only for six months, but for an indefinite time without injury. What one can take indefinitely, another person cannot take even for a very short time. The peculiarities of the patient and the conditions of elimination may entirely alter the circumstances of the case.

Now, in regard to the question whether that dose is too small to cause paralysis, I maintain that, as a matter of fact, if we can believe the reports — of course they are open to doubt also — but there are pretty straight reports which tend to show that the small doses do cause serious symptoms. I refer again to the young woman who took three minims in seven days and became prostrated. Another patient had serious rheumatoid pains by taking two drops of Fowler's solution, and had to take to the bed. There was the man who took six drops for two months, and then a smaller dose for another month, in whom it produced symptoms of irritation of the stomach.

With regard to the question that Dr. Buckingham asked, we have the report of the case of a lady who took a course of arsenic under the observation of a London practitioner who had had great experience in the use of the drug, although it was in 1863, and he may have given very large doses. After a time she was suddenly attacked with paralysis of the hands and feet. In another case a patient took from three to five minims, and suffered paralysis of both arms and legs, and great weakness.

Another patient took arsenic for a time without any symptoms, and then suddenly the symptoms came on. These seem to indicate that we do not know all about the matter yet. It is perfectly fair to throw open the possibility, at any rate, that such results as I record to-night may occur. It is very well known that serious paralyses result from the action of arsenic in wall papers, and yet the amount taken in that way is generally considered pretty small. The person is breathing the air of the room only a certain time, and it may be that the arsenic becomes changed into vaporous form so that it may be absorbed, yet the quantity must be very small or more serious consequences would occur. As a matter of fact, the results are not severe.

With regard to the matter of elimination, it is perfectly true, as Dr. Folsom has said, that elimination is generally considered complete in six weeks, but it evi-

dently is not the case. This woman whom I speak of stopped taking arsenic six months before she died. I say she stopped, for the symptoms came on at that time. At least, we may say that she is not likely to have taken it; and yet, after death, traces of arsenic were found in the viscera, the liver and bones. With regard to the matter of rheumatic neuritis, of course it is perfectly possible that the person may have that disease, but I should be inclined to say that the rheumatic neuritis is about as rare as the arsenical neuritis, if we compare the number of persons who have the rheumatic neuritis in reference to the exposure. The rheumatic neuritis is an excessively rare thing in my experience. Moreover, this neuritis came on in the summer weather of June. So that, while I agree that the case is not by any means proved to be an arsenical neuritis, or that the arsenic found in the urine six months after the last therapeutic dose was taken is the remains of that therapeutic dose, still it seems to me that both of these hypotheses are admissible as such, as a basis for further investigation.

DR. F. S. WATSON then showed the specimens from

A CASE OF TUBERCULOSIS OF THE BLADDER, PROSTATE AND KIDNEYS, ORIGINATING IN TUBERCULOUS EPIDIDYMITIS.[2]

DR. JOHN HOMANS showed a piece of omentum, weighing some two pounds, removed during a McEwen operation for the radical cure of hernia.

MR. H. R. HEYDECKER showed a new trocar which he had invented, for tapping ovarian cysts.[3]

The report of the treasurer, Dr. Buckingham, was then received, and an auditing committee appointed by the chairman. It was voted that an additional assessment of one dollar be made for the coming year.

DR. DAVID W. CHEEVER presented the report of the majority of the nominating committee.

DR. A. B. MORONG presented a minority report. He said: I make this minority report with a little explanation. I differ from the majority of the nomination committee with reference to the nominations of the council only. I agree with them entirely in the nominations for the other officers. The reasons for my dissenting from the nominations that they have made are as follows: In the list passed round the Society will notice that only two changes have been made in the council over last year. One was an addition, necessitated by the increase in numbers, and the other was due to resignation on the part of the last year's incumbent. It will be remembered that in the October meeting of 1886, there was a discussion about more frequent changes. There was brought before the Society an amendment to the By-Laws in reference to the changing of the entire council every five years. After lying over six months until the April meeting, it came up again, and at a very full meeting of the Society a vote was had upon the amendment. It failed of adoption by a two-thirds majority by only five or six, a very large majority of those present voting for it.

Such being the case, I felt it my duty to urge changes which I deemed the majority of the Society desire. It came out in the course of the meeting that there were seven or eight members of the council of the previous year who had stayed away from more than one-half the meetings. Now, in the absence of any rule which forbids any one from serving more than a certain length of time, it seems a fair basis to work upon, if changes were to be made without prejudice, to base our changes on the attendance. It was found that there was one member who had not been present through 1885, another person had been present at only sixteen meetings during his time of service; another, twenty-seven; another, forty-one; another, forty-five; another, forty-seven. There were seven or eight persons who stayed away, whatever the reason may have been; and it seemed to me, in view of the expression of the wish of the majority of the Society, that there should have been more changes, that we might at least have made seven or eight changes; and I have cast my vote in favor of what I deem to be the desire of the majority of the Society.

DR. CHEEVER: May I be allowed to say one word in explanation of the committee's action; I have had the honor to be the chairman of the committee I think for three years. During that time twenty-five per cent. of the councillors have been changed. That is, one-fourth in three years. It seemed to the majority of the committee, after a full discussion the other evening, that it was time to call a halt for a short time, for this year at any rate, because, on looking over carefully the list of available candidates and of suitable persons, it seemed that if we went on the basis of changing as we have been doing, that very many of those gentlemen who have had experience in the Society, and who have been useful, would be left out; and that, moreover, the younger graduates, who have to take their places, would, in the course of five or ten years, have exhausted the list down to the very youngest graduates; so that, if the change were going on so rapidly as that, the council would hardly be considered the representative of the more mature members of the Society.

I admit, we all admit, that attendance at the meetings is very desirable. These councillors are delegates; they are elected to come here and attend to the business of the Society, and certainly they ought to come; and I am happy to say that out of the fifty-two only six or seven can be found who have not attended somewhere from sixty to seventy per cent. of the meetings. Some of the gentlemen, I think, are kept away from the meetings by their engagements, and occasionally, of course, cases of absence occur from sickness. Still, the percentage of attendance is very fair, and it seemed to the committee, that, inasmuch as they had made some pretty sweeping changes since they have come upon the field, it was best to pause for one year, and make only those changes which circumstances rendered necessary in the council this year, namely, one by resignation and one by death; and I think, perhaps, we were entitled to the additional member by the growth of the Society. This is an explanation, only, of our action, and should the Society, at any future time, order differently, of course the committee who may be appointed then, may feel at liberty to make any change which may be proper.

There is another point which I would like to speak of. There are some three or four gentlemen in the list of councillors, who have given a great part of their lives to the use of the Society. They are growing old and infirm. Unless there are especial reasons to the contrary, it seems rather inappropriate to dis-

[2] See page 4 of the Journal.
[3] See Volume cxviii, page 601 of the Journal.

turb them in their relation, unless they wish to be left off. There were several instances of this kind which were considered in the committee and it was thought best to allow time, which very soon will make changes, to make them itself for the coming twelve months.

For President, John Homans; *For Vice-President*, George W. Gay; *For Secretary*, H. F. Vickery; *For Treasurer*, Edward M. Buckingham.

For Librarian, B. Joy Jeffries; *For Commissioner of Trials*, Charles W. Swan; *For District Nominating Committee*, George H. Lyman; *For Committee of Supervision*, F. Minot, H. M. Hodges; *For Committee on Social Meetings*, Vincent Y. Bowditch, Frank B. Harrington, Harold Williams, G. A. Leland; *For Censors*, Elbridge G. Cutler, Charles M. Green, J. H. McCollom, G. M. Garland, H. L. Burrell.

For Councillors, S. L. Abbott, J. Ayer, H. J. Barnes, H. J. Bigelow, C. J. Blake, H. I. Bowditch, E. H. Bradford, F. E. Bundy, J. S. F. Bush, A. T. Cabot, J. R. Chadwick, D. W. Cheever, J. W. Cushing, O. W. Doe, F. W. Draper, S. H. Durgin, T. Dwight, T. W. Fisher, R. H. Fitz, C. F. Folsom, M. F. Gavin, J. O. Green, F. B. Greenough, W. H. H. Hastings, W. C. Holyoke, J. Homans, W. Ingalls, G. F. Jelly, B. J. Jeffries, F. I. Knight, G. H. Lyman, A. E. McDonald, F. Minot, A. Post, C. B. Porter, J. P. Reynolds, W. L. Richardson, T. M. Rotch, G. B. Shattuck, G. C. Shattuck, B. S. Shaw, A. D. Sinclair, A. M. Sumner, C. W. Swan, G. G. Tarbell, O. F. Wadsworth, J. C. Warren, A. P. Weeks, J. C. White, E. N. Whittier, E. Wigglesworth, H. W. Williams.

The Society then proceeded to ballot, and it was announced that the foregoing list of candidates was elected.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING.

The annual meeting of the Council was held at the Medical Library, Boston, on the evening of Tuesday, June 12, 1888. One hundred and nine Councillors were present. The meeting was called to order by PRESIDENT GAGE, at seven o'clock.

The Secretary announced the names of eighty-seven Fellows who had been admitted during the year, and of thirty-three who had died.

FINANCES.

The Treasurer's report showed the year's receipts — including a balance of $2,315.21 from the previous year's accounts — to be $11,314,86. The disbursements amounted to $8,799.15, leaving a balance of $2,515.71. The invested funds of the Society amount, to $33,420.17. The Society now bears upon its catalogue the names of 1,690 members.

The report further stated that assessment dues to the amount of $190.00 have been remitted by vote of the Councillors, upon the recommendation of the Committee on Membership and Finances. Twelve members of the Society have lost their membership by removal from the State, and neglect of their assessment obligations. Since the last annual meeting the names of two Fellows have been dropped from the roll, with the approval of the Council, in accordance with the By-Laws, for five years' delinquency in assessments. Sixteen members have resigned their membership, and four have been reinstated by vote of the Council.

In accordance with the recommendation of the committees on Membership and Finances, reporting through Dr. Minot, it was voted that one-half of the balance remaining in the treasury, amounting to $1,257.85, be distributed among the District Societies.

On recommendation of the same Committee, dues were remitted to several Fellows, others were allowed to resign, and still others were permitted to become retired members.

DR. SHATTUCK reported for the Committee on Publication as follows:

The late Dr. George C. Shattuck, by his last will and testament, gave a fund to the Society, directing that the net income of the same shall be applied from time to time, in the discretion of said Society, or of its government, to the collection and publication annually by some suitable person, of historical or other essays on the climate of the Commonwealth, or on the diseases of its inhabitants, and on such other subjects as the said Society or its government may select.

In 1877 the Council directed the committee to offer prizes for essays from this fund; and the first year four essays were handed in, three of them of such merit that it was very difficult to select the one to the writer of which the prize should be assigned. Subsequently no essays worthy of a prize were offered. Three years and a half ago the Council authorized the Committee on Publications to offer a prize of one thousand dollars for an essay worthy of a prize, on the climate and its modifications as influencing health and disease, or on any of the diseases of the inhabitants of New England, or on any kindred subject; all essays to be handed in on or before March 1, 1888. Only three essays were received, and no one of them was deemed worthy of a prize.[1]

From this experience, and from the experience of members serving on other committees for awarding prizes, the committee unanimously voted to submit the following resolutions to the Councillors:

Resolved, That the Committee on Publications be instructed to provide for a lecture, to be called the Shattuck Lecture, on some subject in accordance with what is specified in the will of the late Dr. Shattuck, the lecture to be delivered at the annual meeting of the Society, the honorarum for it and the publication of it to be defrayed from the income of the Shattuck fund.

Resolved, That the income of the Shattuck fund not required for the expenses of the lectureship shall be used for the printing of the Medical Communications of the Society.

It was voted that the report of the committee be accepted, and that the appended resolutions be adopted.

It was also voted that the committee be not restricted to members of the Society, but have full powers to select such lecturers as they see fit.

Reports were received from the Committee on By-Laws of the District Societies, and from the librarian, DR. E. H. BRIGHAM.

The following communication in behalf of the Committee of Arrangements was received from DR. J. B. SWIFT:

[1] The writer of either of these essays can have his paper returned to him by applying to Dr. G. C. Shattuck, 6 Newbury St., Boston, and giving the motto attached thereto.

"Your Committee of Arrangements has met with considerable difficulty in providing for the social entertainment of the Fellows of the Society at the annual meeting this year, and have been compelled to dispense with the annual dinner.

"The reason for this action was caused by their inability to procure a hall large enough to accommodate the Society; Winslow's Skating Rink, in which the annual dinner has been served for several years, having been taken by the City of Boston for an armory, could not be obtained, and the only remaining hall where a caterer would consent to serve dinner to so large a number is in the Mechanics' Building on Huntington Avenue. The committee, however, did not feel warranted in assuming the expense which would be necessary for this.

"After considerable discussion it was decided to hold a reception at the Hotel Vendome, hoping that by this means a suitable substitute would be provided for the dinner, and that the social element of the meeting would be given more prominence than has been possible in former years where so large a number sat down at the tables.

"Should the Society continue to grow, and the number of members attending the annual meeting increase at the present rate, some other arrangement will soon be necessary in order to accommodate the increased number.

"A proposition came before the committee this year which, should you decide to have the annual meeting hereafter devoted to sectional work, might well be carried out, to wit: Have the meeting held in the Mechanics' Building, using the smaller rooms there for the meetings of the Sections, and have the exhibit take the form of a health or sanitary exibition, which would be open to the general public on the payment of an admission fee. In this way an immense amount of useful information might be disseminated, and a very interesting exhibition be made.

"The social feature of the meeting would in nowise be interfered with, for there would still remain the large hall for a dinner or reception as might seem best.

"Owing to the large number of Fellows who attend the annual meetings, and the difficulties which the committee encounter in arranging for the meeting, it was deemed advisable to bring the subject to your attention."

It was voted to refer the subject to the Committee of Arrangements for next year, with full powers.

THE NEXT ANNUAL MEETING.

It was voted that the next annual meeting of the Society be held in Boston, on the second Wednesday of June, 1889.

ELECTION OF OFFICERS.

The Committee on Nominations reported the following list of candidates for the offices of the Society for the ensuing year, and the same were elected by ballot: Dr. David W. Cheever, of Boston, President; Dr. George Jewett, of Fitchburg, Vice-President; Dr. Frank W. Draper, of Boston, Treasurer; Dr. Charles W. Swan, of Boston, Corresponding Secretary; Dr. Francis W. Goss, of Roxbury, Recording Secretary; Dr. Edwin H. Brigham, of Boston, Librarian.

Dr. Henry P. Walcott, of Cambridge, was chosen Orator, and Dr. James R. Chadwick, of Boston, Anniversary Chairman, for the next annual meeting of the Society.

APPOINTMENT OF COMMITTEES.

The President nominated and the following were appointed to constitute the Standing Committees:

Of Arrangements. — H. C. Ernst, O. K. Newell, V. Y. Bowditch, F. B. Harrington, H. L. Burrell, R. W. Lovett.

On Publications. — G. C. Shattuck, R. M. Hodges, B. E. Cotting.

On Membership and Finances. — F. Minot, B. S. Shaw, J. Stedman, E. G. Cutler, L. R. Stone.

To Procure Scientific Papers. — H. P. Walcott, C. W. Cooper, E. H. Bradford, S. B. Woodward, C. M. Green, L. Wheeler.

On Ethics and Discipline. — G. J. Townsend, G. E. Francis, A. H. Johnson, C. Howe, F. C. Shattuck.

On Medical Diplomas. — W. L. Richardson, A. H. Cowdrey, E. J. Forster.

The President introduced the President-elect, Dr. D. W. Cheever, who made a fitting response.

At 8.30 P. M. the Council adjourned.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON PÆDIATRICS.

STATED MEETING, May 23, 1888.

PROF. V. C. VAUGHAN, of the University of Michigan, Ann Arbor, read a paper on

EXPERIMENTAL STUDIES ON SOME POINTS CONCERNING THE CAUSATION AND TREATMENT OF THE SUMMER DIARRHŒA OF INFANTS.

The subject of summer diarrhœa, he said, he had studied rather from the standpoint of the chemist and physiologist, than from that of the practitioner, and without attempting any exhaustive consideration of it, he would express the views which his investigations had led him to adopt in a series of propositions.

The first proposition was, that the factor most frequently operative in summer diarrhœa is found in the food of the infant. Heat operated in two ways: In the first place, a certain degree of heat was required for the preparation of food before it is taken into the body; this facilitating marked and rapid changes subsequently. In the second place it depressed the nerve-centres, so that the tissues lost their tone, and the normal power of resistance to toxic influences was impaired.

The second proposition was, that the changes in the food which prove harmful are fermentative in character, or, in other words, due to the presence of micro-organisms. It was a universally accepted fact that infants nursed at the breast were very much less liable to summer diarrhœa than those fed upon the bottle. In examining the reasons for this, it was found that there were certain differences in the chemical composition of mother's and cow's milk; but this was not the most potent cause. It had been ascertained that milk taken directly from the healthy animal, whether the human being or the cow, contained no germs whatever, while after it had been allowed to stand for any length of time it invariably contained germs. Thus, he had found that milk taken fresh from the cow could be preserved indefinitely in a sterilized tube, while good market milk, purchased from a reliable dairyman, soon underwent coagulation when kept in the same way.

But if this was the case, why was it that infants nursed at the breast ever had cholera infantum or other diarrhœal disease at all? This might be explained in several ways. In the first place, while a healthy woman's milk contains no germs, an unhealthy one's does; so that if the mother was not in a sound condition, her milk might be affected in the same way

as cow's milk after standing for a greater or less period of time. There were, in addition, many other ways in which germs might find their way into the infant's system; as, for instance, from the breast of a woman who was not cleanly in her habits or who was suffering from sore nipples or diseased breast. Again, few of the articles which infants in tenement houses were liable to come in contact with, were free from germs, and dirty floors were a common source of infection. Lastly, there was always the possibility that harmful germs might be inhaled from the air.

It was true, however, that when germs were contained in the food they were taken into the system in greater quantities than in any other way, and it was remarkable how quickly a few germs would render a large quantity of milk unfit for use. Thus, if half an ounce of contaminated milk were introduced into a gallon of pure milk, and the whole kept in sterilized vessels at the temperature of the body, in a short time the entire quantity of milk would be contaminated and filled with germs. Dr. Vaughan said that he had never seen anything to lead him to suppose that the germs of summer diarrhœa of infants were given off by the lungs and skin. There was abundant evidence, however, that they were excreted from the intestines and kidneys; the frequency of albuminuria offering confirmatory proof of their renal excretion. It was, therefore, highly important that the discharges of such infants suffering from diarrhœa, should always be promptly disinfected. Physiological investigations, he went on to say, showed that the digestion of milk was almost entirely carried on in the small intestines, the stomach having little to do with the process; and clinical observations confirmed the truth of this.

The third proposition was that the micro-organisms which produce simple catarrhal or mucus diarrhœa, are only putrefactive in character; but those which give rise to choleriform or serous diarrhœa are more than putrefactive, being essentially pathogenic. He did not believe in the unity of the microbic agents met with in all the forms of summer diarrhœa. The choleriform disease differed from the catarrhal in its symptoms and its pathology, and there was also good ground for regarding it as differing in its etiology. The poison of choleriform diarrhœa acted directly on the nervous system, probably more particularly on the sympathetic centres; while in catarrhal diarrhœa there was merely a local irritation. A study of the bacteria met with went to show, therefore, that there was more than one affection comprehended in the general designation, summer diarrhœa of infants.

The fourth proposition was that the bacteria prove harmful by splitting up complex compounds and elaborating chemical poisons. With our present knowledge of bacteriology we expected to find the germ of each infectious disease capable of producing its characteristic ptomaines; and he was convinced that the ptomaine of cholera infantum is tyrotoxicon. While the germ producing this ptomaine had not as yet been identified, however, we know something of its characteristics. Thus, it did not act below a temperature of 60° Fahrenheit, and it was anaerobic. That the tyrotoxicon was the ptomaine of cholera infantum was rendered highly probable by the symptoms and anatomical lesions produced on animals by this agent. The following were among the reasons, then, for regarding it as the ptomaine of this disease:

(1) Tyrotoxicon results from the putrefaction of milk, and cholera infantum is almost entirely confined to milk-fed children and those subject to conditions favorable to the development of this ptomaine.

(2) Tyrotoxicon has been found in milk taken by children just before an attack of cholera infantum.

(3) The symptoms of the disease continue to increase as long as the administration of milk is kept up.

(4) The symptoms of the disease are identical with those produced in animals by tyrotoxicon.

(5) The post-mortem results are also identical.

The fifth proposition was that the most efficient preventive treatment will consist in giving attention to the preparation of food, the methods of feeding, and the sanitary surroundings of children under the age of two years. There could be no doubt of the fact that the infant digests the milk of the mother or wet-nurse better than cow's milk. It was also a fact that mother's milk contains more fat than the child can utilize. Artificially-fed infants were more likely to be overfed than those which were nursed, because in the case of the latter the supply of nourishment was limited and not so easily obtained. This overfeeding rendered the child more subject to harmful influences, and the proteids taken into the system which could not be assimulated were constantly liable to contamination by bacteria. Dr. Vaughan then went on to say that he objected to complete artificial digestion of food (1), because, if this were continued for any length of time, the digestive organs would become permanently enfeebled; and (2) because the too rapid absorption of peptones was harmful. The long-continued use of artificially-digested food was, therefore, irrational and unscientific. In order to protect children as far as possible from the danger of cholera infantum, great care was necessary in the preparation of their food, and he had elsewhere laid down certain rules for the preservation of milk which seemed to him of service towards this end. As to the need of attention to the sanitary surroundings of such subjects, it was scarcely requisite to say anything on this occasion, as all were so fully alive to its importance. The sixth proposition was that, in the curative treatment, the destruction of the bacteria which are causing the abnormal fermentation is essential. How, then, could this destruction be accomplished? One of the surest methods of destroying the life of any plant or animal was to completely withhold its food-supply. A radical change of diet, consisting of the entire withdrawal of milk, and the substitution for it of a meat diet, was, therefore, one of the most certain methods of relieving the system of these deleterious bacteria and curing the disease due to their presence. The struggle for existence was probably not without its effect even on micro-organisms. He had found that if contaminated milk was added to beef-tea or to egg-albumen, and the liquid then kept in sterilized vessels at the temperature of the body, the number of bacteria was not increased, thus showing that they could no longer produce their chemical poison, tyrotoxicon. In milk, however, these bacteria found the most favorable conditions for their development and the production of their ptomaine. In summer diarrhœa, and especially cholera infantum, the withdrawal of all milk from the child was, therefore, of the greatest importance.

In addition to this change of diet, various antiseptic agents might be employed in the treatment, and, in order to discover which were the most efficient, Dr. Vaughan had made a series of experiments for the

purpose of testing the action of different germicides or supposed germicides on tyrotoxicon; the drug under experiment being introduced into a bottle containing milk and the poisonous ferment. In this way he ascertained that one part of bichloride of mercury to 2,400 parts of water was efficient in neutralizing the poison. One part of naphthaline to 200 of water was wholly without effect, while one part of sodium salicylate to 200 of water was efficient. It seemed probable in the latter case that the constituents of the salt became separated, and that salicylic acid was, in reality, the active agent. Resorcin in the proportion of one part to 200 of water was, likewise, efficient, but it was inefficient when used in a weaker solution than this.

DR. W. D. BOOKER, of the Johns Hopkins University, Baltimore, read a paper on

A STUDY OF THE MICRO-ORGANISMS IN THE STOMACH AND INTESTINES IN THE SUMMER DIARRHŒA OF INFANTS.

He said that it had been found that in the fæces of all milk-fed infants in health there were constantly present, and in large numbers, two species of bacteria; namely, the *bacterium lactis arogenes* and the *bacterium coli commune*. They were designated as the obligatory milk fæces bacteria, as distinguished from the inconstant bacteria which were found under various circumstances. These were ærobic for the most part, and, as a rule, were somewhat more numerous in the fæces of infants fed on cow's milk than in the fæces of sucklings.

When diarrhœal disease was present, a number of new species of bacteria appeared in the stools, and in a paper which he had read before the Section of Diseases of Children of the Ninth International Medical Congress, Dr. Booker said he had described eighteen varieties which he had observed in the fæces of seventeen children, some of whom were suffering from cholera infantum, some from dysentery, and some from catarrhal diarrhœa, while one was in good health. During the past winter he had investigated the fæces of two additional cases of catarrhal diarrhœa, and he had now to state that he had separated no less than twenty-three varieties of bacteria from the dejecta of nineteen children suffering, with one exception, from diarrhœal disease. Many of the varieties, however, bore a close resemblance to each other, both morphologically and biologically. The fæces of two of the children who had cholera infantum each contained eight varieties.

Having described the microscopical changes and the changes in color produced by the introduction of the various bacteria into pure milk and milk mixed with small and large quantities of bile, Dr. Booker stated that none of the varieties produced diarrhœa in animals, whether introduced into the system by the mouth or rectum, or by intra-venous injection.

DR. L. EMMETT HOLT read a paper on

MICROSCOPIC EXAMINATION OF THE STOMACH AND INTESTINES IN THE SUMMER DIARRHŒA OF INFANTS.

His observations, he said, included eighty-two cases, which he divided into three classes; namely, those in which the disease lasted four days or less; those in which it lasted from four to ten days; and those in which it lasted over ten days. The last class comprised fully one-half of the cases, and the average duration was about three weeks. He then went on to describe in detail the microscopical appearances in the three classes of cases, which were illustrated by a number of carefully prepared plates, and which went to show that the longer the disease lasted, the more profound were the pathological changes in the tissues.

In summing up the results of his researches, he said that in the first class of cases the microscopical examination was very unsatisfactory, and threw no light on the pathological nature of the disease, the appearances differing but little from the *post-mortem* changes often observed, especially in warm weather. In the second class of cases there were extensive enlargement and infiltration of the solitary follicles and sometimes of Peyer's patches, with marked degenerative changes. In the third class the lesions were still more marked, there often being deep ulcerations, and the character of the pathological changes clearly showed why it was that in protracted cases relapses were so apt to occur, and how necessary local treatment was for the cure of the intestinal ulcerations. He had not as yet made a careful study of the micro-organisms found in the inflamed intestines.

The Chairman of the Section, DR. J. LEWIS SMITH, read the report of the microscopical appearances noted by Dr. Wm. H. Welch, now of the Johns Hopkins University, Baltimore, in a case of brief duration which had occurred in his service at the New York Infant Asylum. He then gave the results of an investigation, made at his request by a well-known chemist, of the relative digestive power of the various brands of pepsin now in the market. The same chemist had also made a series of experiments, he said, for the purpose of ascertaining what effect, if any, the different germicidal agents now coming into vogue in the treatment of summer diarrhœa had on the process of digestion, and it was a point of some practical importance to know that these agents do not appear to retard digestion to any extent that would lead us to hesitate on this account to employ them.

DR. GEORGE B. FOWLER referred to the myriads of bacteria found in the intestines, and said that the pathological ferments were all organized, while the physiological ferments were all unorganized. Still, the latter were fully capable of developing active poisons as shown in the cases of xanthin, etc. He had always regarded the gastric juice as possessed of valuable antiseptic properties, so that it stood on guard, as it were, to render more or less inert such poisonous organisms as entered the system by the mouth. Many authorities also taught that the bile had an antiseptic value.

DR. A. CAILLE said that the practical outcome of the evening's discussion was about as follows: If we admit the bacterial origin of the summer diarrhœa of infants, we must admit that its principal cause is to be found in milk; and if this is acknowledged, we are forced to the conclusion that the ordinary methods of preparing and preserving milk are altogether faulty. At the February meeting of the Section on Pædiatrics he had called attention to the apparatus devised by Dr. Soxhlet, of Munich, by means of which the preparing and feeding of sterilized milk can be readily carried out in every family.

Since the February meeting a New York firm, at his suggestion, had prepared an apparatus (which they were now ready to supply in any desired quantity) similar to that of Soxhlet, consisting of a tray

holding ten feeding bottles with combination stoppers, and a pot to boil them in. These, together with extra bottles, rubber nipples, a cleaning brush, and a tin dipper for warming the milk immediately before feeding, were all packed in a box handy for transportation. In using the apparatus each bottle is filled to one-half inch of its neck with the food, properly prepared in accordance with the age and condition of the infant, and a perforated rubber stopper pressed well into the neck of the bottle. The bottles are then set in the tray, and the tray in the pot containing water up to the neck of the bottles, and the water is brought to the boiling point. After the water has boiled for ten minutes each bottle is hermetically closed by pressing a glass stopper down through the perforated rubber stopper. After the boiling has continued for ten minutes longer the tray is lifted out and set aside to cool, after which it should be kept on ice or in a cool place until all the milk has been used. Milk prepared in this way can be kept sweet and pure for any length of time required.

The apparatus, Dr. Caille went on to say, could be purchased for four dollars, but as this was probably too expensive for the poor, he would recommend that a mother who was unable to buy one should get six or eight bottles provided with the combination stopper, and boil the milk for her infant (as prepared for use) in them.

DR. A. SEIBERT said that he had no doubt that the proceedings of this evening would constitute a stepping-stone towards the attainment of a really scientific knowledge of the origin of summer diarrhœa. He was gratified to find that Professor Vaughan had arrived at the same conclusion as himself, that 60° Fahrenheit was the boundary-line beyond which the fermentation of milk commenced.

DR. J. E. WEEKS said that a year ago he had made a series of experiments in regard to the action of different agents on the pus germ. He found that salicylate of sodium was inert, while salicylic acid was actively germicidal; and he believed, therefore, that Professor Vaughan was right in concluding that in his own experiments the salts became changed, and that its germicidal value was really due to the salicylic acid that was liberated. Naphthalin he found germicidal in rather strong solutions, while bichloride of mercury stood very high. Nitrate of silver also stood high.

DR. VAUGHAN, in bringing the discussion to a close, said that in his own experiments it was probable that the lactic acid present set some of the salicylic acid free from the sodium salicylate. In Dr. Weeks's experiments, there being no such agent present, the salt would naturally remain unchanged. As to the practical use of germicides in the treatment of summer diarrhœa, the dose of the bichloride of mercury required would be about one twenty-fifth of a grain, and as this seemed rather large for young infants, it would, no doubt, be safer to give five grains of salicylate of sodium, which, according to his tests, was the dose of this agent required for the purpose desired.

DR. SMITH having inquired whether it was a fact, as supposed by some, that calomel was changed into the bichloride of mercury after being taken into the system, Dr. Vaughan replied that this was undoubtedly the case with a certain proportion of the amount taken, and it seemed probable to him that the change was especially likely to take place when the calomel was given in small doses.

Recent Literature.

Atlas of Venereal and Skin Diseases. Edited by PRINCE A. MORROW, A.M., M.D. Fasciculi I, II and III. New York: William Wood & Co., 1888.

The scheme of this work, which is to be published in fifteen parts, each part containing five plates, with accompanying text, is an excellent one; namely, the selection of plates from different atlases, their reproduction and collection in an American edition. The principal sources of supply will be the well-known and standard atlas of Kaposi and Neumann. Additional specimens are to be contributed from their collection of original drawings by other distinguished dermatologists in this country as well as abroad. The conception of the work is good, since it means selection and combination of the best, and its execution, as represented by the first three numbers, is deserving of high praise. In these numbers are shown varieties of the local venereal ulcer, and of the initial lesion of syphilis, together with some of the earlier cutaneous manifestations of the disease. The plates are taken, for the most part, from Kaposi, a few figures being supplied by Hutchinson's collection. A careful comparison of the originals, so far as Kaposi's plates are concerned, with their reproductions, shows the latter to be faithful copies, and, if anything, better lithographs. The lithographic work also in the copies of Hutchinson's figures is particularly fine. The difficulty of doing this sort of work well is great, demanding time and attention to detail, and if the standard set by the first three numbers is maintained, an excellent atlas of cutaneous and venereal disease will be the result. G. H. T.

Diseases of the Heart and Circulation in Infancy and Adolescence. By JOHN M. KEATING, M.D., etc., and WILLIAM A. EDWARDS, M.D., etc. pp. 211. Philadelphia: P. Blakiston, Son & Co.

This book is made up of a series of articles which appeared in recent numbers of the *Archives of Pædiatrics*, and are now collected. The first question which naturally presents itself to the mind of the reader is: what special peculiarities, physiological and pathological, of the circulatory apparatus do infancy and adolescence present? The answer to this question is obvious. The chief and only important difference between children and adults in this respect lies in malformation of the heart and great vessels, and the consequences which this entails. Endocarditis and pericarditis are much the same clinically and pathologically at all ages, while primary degenerative changes of the heart walls are extremely, secondary comparatively, rare in the young subject.

Of the 211 pages in the book, twenty-seven, including three of a valuable bibliography, are devoted to the fœtal circulation, congenital disease, and malformation; while thirty-two pages are given to diseases of the blood, comparatively rare in early life, and during that period in no wise peculiar. Hæmophilia is an exception. The authors lay stress on the frequency with which this remarkable proneness to hæmorrhage, with regard to the intimate nature of which we are so ignorant, is hereditary, and also on its rarity in females, but have forgotten to mention the very interesting peculiarity of hereditary transmission shared by hæmophilia with color-blindness and pseudo-hypertrophic paralysis, that while the fe-

male members of a family escape in their own persons, they transmit the constitutional vice.

As far as the chapter on congenital disease goes, it is in the main clear and accurate enough. The authorities are not unanimous as to the relative value of the two factors — inflammation and malformation — in the production of congenital cardiac disease, but there certainly seems good reason to think that fœtal endocarditis is especially apt to attack a valve which is malformed; that is, is often secondary.

The situation of the apex-beat higher and farther to the left in children than in adults, the heart being placed more transversely on account of the high stand of the diaphragm, is well brought out, and should be known by all.

The chapter on treatment strikes us as vague and unsatisfactory. The paper and print are good, but the printer has been allowed to take liberties with the names of continental writers. The photographs bound into the book do not seem to us to enhance its value. They are in marked contrast with the simple colored cut of the fœtal circulation borrowed from Cazeau's and Tarnier's obstetrics.

A Manual of Medical Jurisprudence, with special reference to Diseases and Injuries of the Nervous System. By ALLAN MCLANE HAMILTON, M.D. New York: E. B. Treat. pp. 390.

This book is the work of an author of wide experience as an alienist. He sets before his readers his views upon a series of subjects having most important medico-legal relations. Insanity, hysteria and "hysteroid" conditions, epilepsy, alcoholism, cranial and spinal injuries are discussed in a way to serve fairly the purpose announced in the preface — that the volume is "an elementary treatise and book of reference for lawyers and doctors." But the work, though interesting, seems to us to be lacking in those qualities which, if present, would give it permanent value. It is crude and unfinished. The effect of the various chapters and sections is that of patchwork. There is a want of symmetry and deliberation in the workmanship. The volume is a scrap-book rather than a treatise; its parts lack cohesion. The subjects pertinent to the scope of the author's design, as set forth in the preface and title, are not elaborated in such a way as to satisfy the discriminating reader, and matters not germane are interpolated without good reason. Many pages are devoted to malingering and feigned diseases, and a chapter is given to a discussion of the methods and post-mortem diagnosis of suicide; it is difficult to see the relation of these topics to diseases and injuries of the nervous system, or to comprehend the kinship of these latter matters to the question (page 194), "can persons be robbed while under the influence of chloroform?"

The work, too, shows considerable evidence of hasty and careless preparation. Besides the absence of proper method and arrangement in rhetorical construction, the pages are marred by numerous grammatical errors and heedless omissions, which are a serious and inexcusable blemish in a composition of this kind. The volume shows a stamp upon its cover to indicate that it is one of a series of "medical classics." The critical reader, however, will hardly fail to observe that much painstaking revision and reconstruction are required to bring the text up to a level that truly deserves the descriptive title "classical."

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 5, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

ANNUAL REPORT OF THE BOSTON CITY HOSPITAL FOR 1887.

THE annual report of this Hospital shows a continued increase in the number of patients treated. The whole number under treatment in the Hospital during the year was 5,937, being 569 more than were treated during the preceding year. The largest number in the Hospital on any one day was 392, the daily average being 354. The average cost to the city for the board of each patient was $7.41 per week.

Of these patients, 790 were accidentally injured, and the severity of the accident cases is shown by the fact that 185 patients died within forty-eight hours after admission. The growth of the Hospital work is illustrated by a comparison with the accidents of the first full year of the Hospital's existence — 1865 — when the admissions for accidents were 242. In addition, 14,318 were treated in the out-patient department. The statistics show a high death-rate, $10\frac{4}{10}$ per cent. If from the total number of deaths we deduct those brought to the Hospital in a dying condition, the annual mortality is reduced to $7\frac{3}{10}$ per cent., which is still high enough to provoke inquiry. The greatest mortality was due to diphtheria. According to the tables, there were on the medical side of the Hospital 105 cases of diphtheria, with 31 deaths; and on the surgical side 77 cases, with 57 deaths, a grand total of 81 deaths from that dread disease. The ratio of deaths to cases admitted is probably greater even than these figures show, as cases are occasionally admitted to the medical side and afterwards transferred to the surgical department for tracheotomy, and in such cases would be likely to figure twice among admissions and but once among deaths. These cases of diphtheria are undoubtedly the worst that the city affords, many of them being admitted simply because the hospital gives them a "last chance," and occasionally we believe a case is very properly forced into the hospital by the Board of Health, for the safety of its neighbors.

Where active interference has been necessary, tracheotomy and intubation have been the resort about an equal number of times. Intubation was done 30 times, with 22 deaths; tracheotomy was done for diphtheria 37 times, with 30 deaths, showing a little more favorably for intubation, but the figures are too small to give any reliable comparisons.

Phthisis pulmonum is credited with 55 deaths. These were probably hopeless, or nearly so on admission, many of them being admitted with a view simply to soothing their last days.

There were 256 cases of typhoid fever, and 43 deaths. During the last season the summer tent service was enlarged by additional tents, and medical cases, especially typhoid fever, were treated in them, but no exact data exist to show whether such cases did better than in the wards.

The tables of surgical operations have recorded against many of the deaths a word of explanation giving some facts as to the cause, and the absence of septicæmia and pyæmia is quite striking. The table of surgical diseases shows that a few such cases were admitted but as a sequence of operations the disease was practically unknown during the year.

The Hospital has added to its capacity by two new buildings for contagious diseases, which were not opened at the time the report was written. The two buildings are practically alike, differing only in a few details. They occupy space formerly vacant, on the medical side. Each building is 138 feet long by 42 feet wide, is one-storied in centre for 75 feet; the end portions (31 feet each) having two stories. In planning these buildings for the special use of contagious cases, it was intended to so arrange the wards that in each building there might be accommodations for each sex in open wards, and also in isolating or private rooms. Any satisfactory plan to meet this requirement involved a radical change in arrangement from any in the buildings now erected.

The buildings are entered on the main floor by three doors upon the side, instead of by one end door, as in the other one-story buildings. Each building may be said to be divided into five sections: the centre section contains the service or duty rooms; on either side is an open ward, 25 feet by 35 feet, intended one for either sex, and accommodating eight adult patients or ten children. At each end is a group of three isolating rooms on the ground floor.

At either end of each building in the second story is a small group of rooms, 42 feet by 31 feet, accessible by stairway, and so arranged as to be used as an annex to the ward, or they may be shut off from the ward, and be entered by an outer door leading to the lateral corridor. The arrangement is such that it may be used for private patients, to give increased accommodations in time of epidemics for convalescent patients from the main ward, or for cases of mixed contagious diseases. This group consists of three rooms, capable of accommodating six patients, having serving, toilet, and bath rooms, and the complete outfit of a small isolating ward. These contagious wards were greatly needed.

The Trustees express the hope that the Hospital may be at some time in the near future endowed by the city with a much needed convalescent home.

The list of bequests to the Hospital shows that the last bequest was dated 1875.

HISTORY OF A MEDICAMENT.

UNDER this title, Jules Cyr, in a recent spirited and humorous publication ("*Scènes de la Vie Médicale*") takes off one of the medical fashions of the times. Many old medicines have gone out of use and the confidence in others is shaken, but while in some quarters the materia medica is undergoing (as it deserves) a careful weeding, in others there is a rage for therapeutic novelties which often redounds more to the profit of the pharmacist (who knows how to turn to the best account the fleeting reputation of a new drug), than to that of the physician or his clientèle.

Ganivet and Lapozème had been fellow-students at the Ecole de Médecine. Both were located in the metropolis; the one was hospital externe, the other, interne in pharmacy; both were ambitious and impecunious. Ganivet had no notion of seeking for fortune and influence by patient waiting, or by the ordinary routine of dull toil; he aimed to find a "specialty" that would at once bring him fame and fortune. A happy inspiration seized him; he would discover a new medicament, have it duly tested physiologically and clinically, get the medical journals to trumpet it and thereby create a demand, patent it and thereby enjoy the monopoly of a lucrative and useful product, and the consciousness of having done something to lessen the sum of human ills. Where was he to look for the new pharmaceutical agent that was to so interest and arouse the medical profession in the old world and the new? Naturally in the "aromatic series" that "mine of specialties" from which so many new antiseptics and antipyretics had been derived, and which was doubtless yet far from being exhausted. His friend Lapozème, the chemist, could here render him valuable service. To him he communicated his plan. By a subtle combination of analytical and synthetical processes, all belonging to the domain of the laboratory, the new pharmaceutical wonder was to be teased out of the arcana of nature. There must be some physiological experiments by gentlemen holding an official position, to test its properties. Then would come the usual "notes" to the Society of Biology, "notes" to the Institute, experiments on hospital patients, experiments in private practice. Liberal trial samples would be sent to medical celebrities in different parts of the country, with printed circulars, containing the endorsement of the renowned clinical chief of the great Hôpital des Malades, etc.

To shorten the story, the "mine" of the aromatic series was "explored" with diligence, and by the skil-

ful combination of several rather complex organic radicals, the sought-for product was obtained. Ganivet, by a little clever wire pulling, got the appointment of deputy preparator to the Laboratory of New Medicaments, where he had at his disposal a sufficient number of dogs, hares, guinea-pigs, and frogs for experimentation. The new drug was duly tested and found to have a marked action on the heart, in small doses increasing the vital properties of that organ; in large doses tetanizing it. It therefore received the appropriate name *Cardiosthenine*. "Notes" and "Communications" were at once sent to the learned societies. In the opinion of those who had experimented with the new chemical agent, it was far superior to digitalis, which it must eventually replace in the practice of progressive physicians.

Cardiosthenine was received with favor, and even with enthusiasm and furor, by the medical profession. The wary proprietors, who were careful to protect their own interests by patenting the name, were able without much difficulty to obtain the requisite clinical experimentation and a goodly number of emphatic testimonials. The celebrated Dr. Simon Levi, clinical chief of the Hôpital des Malades, who had had the honor of attending the late General B—— in his last illness, gave the weight of his influence in favor of the new medicament. He caused it to be thoroughly tested in five thousand cases, and with uniformly favorable results: elaborate reports of these trials were published under his own name, or embodied in theses by his pupils. Communications by other authorities were presented to the "Institute" and "Academy," and these were reproduced by all great medical journals, at home and abroad. In short, as has been the case with many other new medicaments whose *début* has been suitably trumpeted, *the results noted were always favorable at first.* It is needless to say that the demand for their product more than satisfied the most sanguine expectations of the proprietors, the sales being for some time unprecedented, and the profits accruing therefrom (all competition being rigidly excluded) being necessarily liberal.

To be sure, the ultimate results, it must be confessed, were somewhat disappointing, as the proprietors found after they had exploited their "cardiosthenine" for all that it was worth; and another melancholy fact was added to that long chapter of human history which tells how easily the best of men are sometimes imposed upon.

EXPERIMENTAL RESEARCHES RELATIVE TO THE ACTION OF MEDICAMENTS ON THE BILIARY SECRETION, AND THE ELIMINATION BY THIS SECRETION.

DRS. PREVOST and Binet have communicated a note to the Academy of Sciences relative to the cholagogue action of medicaments, and their elimination by the bile. These experiments were made on two dogs on which they had produced a biliary fistulæ, and which were kept several months under observation. The following is a resumé of their studies:

(1) "In confirmation of the experiments of Röhmann, our animals with the biliary fistulæ have been kept in good health by excluding from their food fats which pass out almost in their entirety in the stools, where their presence is easily detected.

(2) "The quantity of bile augments somewhat with food, especially after the ingestion of peptones. Fats, on the other hand, do not produce any augmentation in the flow of bile. Cold or warm water only produce slight increase in quantities of 150 cc. to 200 cc. Copious lavements of cold water, recently recommended in jaundice, do not modify the biliary secretion.

(3) "As for the elimination by the bile of medicaments introduced into the organism; this is always inconsiderable.

(4) "There is no constant relation between the elimination of a substance by the bile and the effect which it may have in increasing the biliary secretion."

MEDICAL NOTES.

— The thirty-seventh meeting of the American Association for the Advancement of Science will be held at Cleveland, Ohio, from Wednesday morning, August 15, until Tuesday evening, August 21, 1888.

— Dr. Squibb gives the following list of the antipyretic drugs in common use, with the price per ounce, and the statement as to whether or not it is patented

Sulphate of quinine (best makers) about	$0 40
Tartrate of chinoline	70
Resorcin	30
Salicylic acid, patented	20
Kairin, patented	2 00
Antipyrine, patented	1 25
Sulphate of thallin, patented	1 75
Antifebrin, 30c. per oz., or as acetanilide	15
Salol, patented	40

— A writer in the *Indian Medical Gazette*, of Calcutta, is publishing a medical history of our War of the Rebellion, in which occurs the following: "With reference to the disease called 'cholera morbus,' of which 26,347 cases, with only 305 deaths, are said to have occurred, it is doubtful whether they would not have been more appropriately placed under some other head of disease. I find numerous non-fatal cases of 'cholera morbus' recorded in the returns from the commencement of the war some years before the fourth 'invasion' of the disease occurred in America. It is hardly credible that the disease known to us as cholera would have occasioned so few deaths in so many cases."

— The son of a prominent citizen of Dublin consulted an eminent throat specialist for an affection of the larynx. A tumor was discovered, and portions excised for microscopic examination, the physician meantime assuring the patient that appearances pointed to the growth being entirely benign. But the patient had become so thoroughly demoralized by reading the newspaper literature of the late German Emperor's

case and by other quasi-medical reading, that he committed suicide in a fit of depression. Another instance of the possible ill effects of scattering detailed bulletins of the illness of the great, where ill-balanced minds cannot avoid seeing them.

— Recent explorations at the Island, of Cos have as we learn from the *Medical News*, unearthed the site of the renowned temple of Æsculapius, the third in prominence in the mind of the Greek world. The only ones that were held in higher esteem were the temples at Epidauros and Athens. An altar has been found, and a marble serpent, the well-known attribute of the god of medicine. The description that Strabo gives of the temple at Cos would indicate the possibility of a rich harvest if systematic excavations are carried on at this site. He says that its shrines were full of votive offerings, including priceless works of art, and its walls abounded in inscriptions recording the cures wrought there, which Hippocrates is said to have studied, and from which he learned much of his medical lore. The excavations at the Asclepeion of Athens have yielded valuable results, but much remains to be learned concerning the cult and ritual of Greek medicine, which can be discovered only by the bright spade of the scholarly explorer.

— The *Medical News* chronicles the intended erection by the Jefferson County (N. Y.) Historical Society of a monument to the discoverer of chloroform, Dr. Samuel Guthrie. Dr. Guthrie was born in 1782, his father having been a physician of Brimfield, Mass.; he died in 1848. During the War of 1812 he was examining surgeon, and did chemical work for the military posts in northern New York. In 1817 he took up his residence at Sackett's Harbor. He published in *Silliman's Journal* for October, 1831, an article describing the preparation and properties of a "Spirituous Solution of Chloric Ether." The ether was made by distilling chloride of lime with alcohol. His paper was in the hands of the publisher as early as May 8, 1831, and was completed some months before that date. These data conclusively establish the priority of the American discovery of the world's great anæsthetic, since Liebig had not published his account until November, 1831, and Soubeiran's did not appear until January, 1832. The race between these three independent discoverers is a close one, but to Guthrie our contemporary awards the honor of first making and describing the substance which we now know as chloroform — a name originated by Dumas in 1835. It is a curious fact that Guthrie, during forty years of his life, devoted much time and thought to the improvement of gunpowder, and it is quite possible that both that destructive compound and the anæsthetic that was to be, were in hand at one and the same time.

BOSTON AND VICINITY.

— By a will lately made the Boston Medical Library Association will receive a bequest of $10,000 at some future time.

— Mrs. Sarah Jane Robinson, the Somerville, Mass. poisoner, has, after the rejection of her motion for a new trial, been sentenced to be hanged in November next.

NEW YORK.

— On the 28th of June, Mr. D. O. Mills formally transferred to the city the new training school for male nurses which he has erected at his own expense in the grounds of Bellevue Hospital. The building, which is of Carlisle stone and red brick, with terra cotta trimmings, is in the form of an L, five stories and a basement in height, and has a frontage of 75 feet on Twenty-sixth Street, and 80 feet on the East River. The two upper floors are to be devoted to the hospital museum. On the occasion referred to the principal address was delivered by the Hon. Chauncy M. Depew, and at its conclusion he read a letter from Mr. Mills to Mayor Hewitt, making over the building and its appliances to the ownership of the city, in which the donor said: "In the great development of means for caring for the helpless sick which marks the present century no want has been more felt than that for trained nurses. . . . The Training School for Female Nurses was a great gain. Personal observation of the good it had done led me to think that an equal service might be rendered by an institution for the training of male nurses. The humane work of the physicians in charge of Bellevue and other city hospitals could thus be efficiently supplemented, and the sufferings of the poor under their care alleviated, while the community would gladly employ all the male nurses the hospitals can spare, and so enable the students thus trained to make the vocation of nursing their life-work." The total cost of the building as completely equipped and furnished by Mr. Mills was about $100,000.

Miscellany.

CONTINUED AND REMITTENT FEVERS.

The following circular has been issued from the office of Supervising Surgeon-General, Marine Hospital Service:

To Medical Officers and Acting Assistant Surgeons: With a view of formulating a more precise symptomatology of the "continued" and "remittent" fevers; from and after July 1, 1888, you are directed to take full and accurate notes of all cases of "continued and "remittent" fevers treated by you among patients of the Marine-Hospital Service, and to make special semi-annual reports of all such cases to this office.

The cases of fever should be classified, as far as practicable, according to the symptoms in each case, into simple continued, enteric, remittent, etc., and every symptom noted.

The presence or absence of the following symptoms relative to enteric fever should be carefully noted, together with the dates of their respective appearance: eruptions; diarrhœa; tympanites; intestinal hæmorrhage; perforation of intestines; peritonitis; necropsy; temperature range; enlargement of spleen; delirium (character); mode of onset (gradual or sudden,) presence or absence of initial chill; presence or absence of intestinal lesions, and if present, give exact location.

CASCARA SAGRADA IN RHEUMATISM.

H. T. GOODWIN, M.D., Assistant Surgeon, United States Marine Hospital Service, writes as follows in the *New York Medical Journal*, under date of June 9, 1888.

The effect of cascara sagrada in rheumatism I discovered by accident. About three months ago, I was attacked with severe rheumatic pains in my shoulder, the slightest motion causing intense pain. The third day of the attack, I commenced taking as a laxative ten drops of the cascara, t. i. d. The first morning after taking it the pains were so much less severe that I could move my arm freely. The day following I was entirely free of all discomfort.

Although, as I have intimated, I had not taken the cascara with any idea of relieving the rheumatism, it occurred to me a few days later that possibly the sudden subsidence of pain might have been due to the drug. There being a few cases of rheumatism in the wards, I determined to try to verify my suspicions. Discontinuing the salicylates, iodides, etc., which these patients were taking, I substituted ext. carcaræ sagradæ fl., i. c. c., t. i. d. The result astouished me. Within twenty-four hours there was marked improvement in every case. One case is especially worthy of notice: The patient was a Swedish sailor, who had been admitted three months previously. He suffered intensely, and although almost everything had been given from which relief might be expected, his suffering was not allayed. For a day or two after admission he improved on large doses of salicylate of sodium, but subsequently the pains returned as badly as ever, and the salicylate had no further beneficial effect. Iodide of potassium was given several different times, but, owing to an idiosyncrasy, could be continued only two days at a time, a profuse rash making its appearance over the patient's entire body, the pains remaining as acute as ever. They were not confined to any two or three joints, but felt in all, being more severe, however, in the wrists, finger-joints, and ankles, all of which sometimes became œdematous. On the evening of February 5th, I commenced the exhibition of fifteen-drop doses of cascara sagrada three times daily. The following morning he was about the same; the second day he was much better; on the seventh he was so far recovered that he asked and obtained permission to walk out. From this on he continued to improve steadily, and on the 17th of February was discharged, recovered.

I have since used the cascara in fully thirty cases, some ten of which were in out-patients, and, with the exception of three or four in which there was a syphilitic taint, I have obtained the most satisfactory results. I commenced with 1 c. c., t. i. d., and have never had to increase it beyond 1.5 c. c., and even to this extent in but two cases. I have seldom had to wait beyond twenty-four hours for beneficial effects. In two cases I had to stop it temporarily, owing to its opening the bowels too freely. In such cases I would suggest that one of the preparations of iron be given (separately) at the same time. I usually combine it with syrup of glycerine in equal parts, and instruct the patient to take from thirty to forty drops in water. In one case in which neither it or the salicylate of sodium appeared to give much benefit, I combined the two with good effect.

It is but seldom the bowels are opened too freely by it, the cases above referred to being the only ones I have so far observed.

I am not able to explain the action of the drug in relieving rheumatism; I leave that to other observers. I write this in the hope of inducing other medical men to use the cascara, report their experience, and indicate, more particularly, in what class of cases they have found it of most benefit.

EARLY RUPTURE OF A TUBAL GESTATION SAC: OPERATION.

An interesting case is described by Dr. J. Zucker, of Berlin (*Centralblatt fur Gynäk*, No. 15, 1888, and *London Medical Recorder*, May 21, 1888). Dr. Zucker was called in on February 17, 1888, to an indigent woman, aged 32. She was suffering from severe pains in the loins and hypogastrium. She had borne two children, and had had one miscarriage; but the date of her last confinement was not stated. The last period was "in December or in January." On February 12th severe abdominal pains set in and lasted for two hours, passing off after purgation by drugs. The patient resumed work, but the pains returned on the 17th. The pulse was weak, the tongue dry. The abdominal walls were very tense, but an indistinctly circumscribed soft mass could be felt to the left of the cervix. The parts were very tender. Symptoms of severe intraperitoneal hæmorrhage set in during the night, and much time was lost in transferring her to Dr. Veit's wards. At 2 P. M. on February 18th Dr. Veit operated. The patient was pulseless and slightly delirious. Even under chloroform no circumscribed tumor could be felt. On opening the peritoneum blood spurted out freely. Nearly four litres of fluid blood had to be rapidly cleared away. The left appendages were carefully explored but found normal, and the right fimbriæ floated freely in the peritoneal cavity. On prolonged scrutiny the bleeding was at last found to proceed from a rent, two inches long and three-fifths of an inch wide, at the junction of the inner and middle third of the right tube. Fortunately, in clearing away the mass of clots around the rent, an entire minute ovum was discovered. The tube was speedily ligatured on each side of the rent, and the pedicle encircled by a transfixing suture (*rings umnäht*). The abdominal wound was then closed, and about a litre of bloody fluid was left in the peritoneum, the operator hoping that it would be absorbed. A compress was applied to the abdomen, the patient rallied for awhile, but died rather suddenly twenty-one hours after the operation. The ovum was found to be p rfectly fresh, and could not have exceeded the third week of its development. The tubal sac was "at the most" not larger than a hazel-nut. No disease of the adjacent tubal mucous membrane could be found, The very early rupture and the profuse hæmorrhage from so small a rent were remarkable features in this case. Dr. Veit has operated in ten cases of tubal pregnancy. In three rupture had taken place, only one of these recovered; all the seven cases uncomplicated by rupture recovered. That abdominal section should be undertaken as speedily as possible when acute symptoms of intraperitoneal hæmorrhage occur after a distinct history of sudden cessation of the catamenia for two or more months, there can be little doubt.

Correspondence.

POSTURAL TREATMENT OF CONSTIPATION.

PAWTUCKET, R. I., June 30, 1888.

MR. EDITOR, — The essayist on "Postural Treatment of Constipation" did not, I think, exhaust his theme. The seat of the water-closet should be low, and made to fit the parts anatomically. Through a board of proper thickness make a circular aperture of suitable dimensions, and then thin down laterally for some two inches, and scarf off on the under side, in front and rear, leaving the hole, when seen in profile, circular. That plan of a seat is comfortable, and it will give all the advantages of the "squat." In regard to a woman in travail, more than thirty years ago an "obstetrical chair" was offered in this market, which had all the aids to expedite labor claimed for the device brought to notice at the late medical meeting of the Massachusetts Medical Society. No one piece of carpentery is more awkwardly done than making water-closet seats. Why, within a short time, in a first-class house in Providence, the aperture I noticed is like the section of a goose-egg, and it must be very uncomfortable to defecate sitting upon it.

Yours truly,

J. O. WHITNEY, M. D.

— The Board of Health of New South Wales has reported adversely upon the proposition to rid Australia of its pest of rabbits by the introduction of the fowl-cholera, according to the proposition of M. Pasteur. They fear that the remedy might "get away" from them, and, like a prairie fire, prove to be entirely beyond the control of its originators. As far as concerns such remedies, they prefer to bear the ills they have than fly to others that they know not of.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 23, 1888.

Deaths reported 2,998: under five years of age 1,154; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) — consumption 321, acute lung diseases 238, diarrhœal diseases 427, diphtheria and croup 112, scarlet fever 38, measles 34, typhoid fever 28, whooping-cough 25, malarial fever 24, cerebro-spinal meningitis 20, erysipelas five, puerperal fever five, small-pox two. From measles, New York 25, Chicago, St. Louis, and Washington two each, Baltimore, New Orleans and Lawrence one each. From typhoid fever, Chicago five, Cincinnati four, St. Louis, Boston and New Orleans three each, Baltimore and Washington two each, Pittsburgh, Nashville and Lawrence one each. From whooping-cough, New York 10, Chicago five, Washington four, Boston three, Baltimore, Cincinnati, and Pittsburgh one each. From malarial fever, New Orleans seven, St. Louis six, Baltimore four, New York three, Washington two, Nashville and Charleston one each. From cerebro-spinal meningitis, Chicago five, New York and Washington four each, Pittsburgh and Nashville two each, St. Louis, Cincinnati and Holyoke one each. From erysipelas, New York three, Chicago and Baltimore one each. From puerperal fever, Chicago four, St. Louis one. From small-pox, New York and St. Louis one each.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending June 9th, the death-rate was 16.2. Deaths reported 2,915: iniants under one year of age 648; acute diseases of the respiratory organs (London) 185, whooping-cough 81, diarrhœa 42, measles 10, scarlet fever 36, diphtheria 31, fevers 24, small-pox (Sheffield six, Preston four, Bristol one) 11

The death-rates ranged from 12.5 in Birkenhead to 25.0 in Manchester: Birmingham 19.5; Bradford 14.3; Brighton 15 7; Hull 14.7; Leeds 15.5; Leicester 16.4; Liverpool 14.8; London 14.9; Newcastle-on-Tyne 12.8; Nottingham 12.9; Portsmouth 15.0; Sheffield 18.0; Sunderland 18.2.

In Edinburgh 17.7; Glasgow 20.9; Dublin 21.7.

The meteorological record for the week ending June 23, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, June 23, 1888.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 22, 1888, TO JUNE 29, 1888.

McPARLIN, T. A., colonel and surgeon, U. S. Army. Granted leave of absence for one month with permission to apply for an extension of one month. S. O. 52, Department of the Platte, June 20, 1888.

BROWN, J. M., major and surgeon. Will take charge of the office and duties of the Medical Director, Department of the Platte, during temporary absence of Col. McParlin. S. O. 52, Department of the Platte, June 20, 1888.

OWEN, WM. R., Jr., captain and assistant surgeon. Ordered to Fort Leavenworth, Kansas, for duty. S. O. 148, A. G. O., June 27, 1888.

WOODHULL, A. A., major and surgeon. Granted leave of absence for three months to take effect about July 10, 1888. S. O. 148, A. G. O., June 27, 1888.

WOOD, MARSHALL W., captain and assistant surgeon. Ordered to Fort Randall, D. T., for duty. S. O. 147, A. G. O., June 26, 1888.

SHANNON, WM. C., captain and assistant surgeon. Ordered to Fort Meade, D. T., for duty. S. O. 147, A. G. O., June 26, 1888.

McCREERY, GEO., captain and assistant surgeon. Ordered to Fort Warren, Mass., for duty. S. O. 147, A. G. O., June 26, 1888.

So much of Paragraph 3, S. O. 142, A. G. O., June 20, 1888, as relates to Captains George H. Torney and George McCreery, assistant surgeons, is revoked. S. O. 147, A. G. O., June 26, 1888.

GANDY, CHAS. M., first lieutenant and assistant surgeon. Granted leave of absence for three months to take effect on or after July 5, 1888. S. O. 145, A. G. O., June 23, 1888.

POINDEXTER, J. D., first lieutenant and assistant surgeon. Granted leave of absence for one month. S. O. 55, Department of Dakota, June 18, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING JUNE 30, 1888.

MOORE, A. M., surgeon. Ordered to Naval Station, New London.

AUSTIN, A A., passed assistant surgeon. Detached from "Gedney" and wait orders.

OWENS, THOMAS, assistant surgeon. Detached from Naval Station, New London, and to Coast Survey Steamer "Gedney."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JUNE 30, 1888.

VANSANT, JOHN, surgeon. Granted leave of absence for ten days, June 25, 1888.

MEAD, F. W., passed assistant surgeon. Granted leave of absence for thirty days, June 28, 1888.

APPOINTMENTS.

BOSTON CITY HOSPITAL.

The trustees of the Boston City Hospital have made the following appointments: J. Orne Green, M.D., Visiting Aural Surgeon; E. D. Spear, M.D., and George A. Leland, M.D., Aural Surgeons to Out-Patients; Henry W. Kilburn, M.D., Assistant to the Ophthalmic Surgeon.

BOOKS AND PAMPHLETS RECEIVED.

Nineteenth Annual Report of the State Board of Health of Massachusetts. Boston, 1888.

Food Laws. By Henry Leffmann, M.D. Philadelphia, 1888.

Medical Publications; Harvard Medical School. 1887.

Merrow's Atlas of Venereal and Skin Diseases, No. 5. New York: William Wood & Co.

Massachusetts College of Pharmacy. Twenty-first Annual Catalogue. 1887-88.

The Relation of Alimentation and Disease. By J. H. Salisbury, A M., M.D., LL.D., Member of the Philosophical Society of Great Britain, etc. New York: J. H. Vail & Co. 1888.

Contributions to Clinical and Practical Medicine. By A. T. H. Waters, M.D., Fellow of the Royal College of Physicians of London, etc. London: J. & A. Churchill. 1887.

The Electric Illumination of the Bladder and Urethra as a Means of Diagnosis of Obscure Vesico-Urethral Diseases. By E. Harry Fenwick, F.R.C.S., etc. With thirty illustrations. London: J. & A. Churchill. 1888.

The Physician's Leisure Library, No. XI. The Disorders of Menstruation. By Edward W. Jenks, M.D. Detroit: George S. Davis. 1887.

A System of American Obstetrics. By American Authors. Edited by Barton Cooke Hirst, M.D., Associate Professor of Obstetrics in the University of Pennsylvania, etc. Volume I. Illustrated with a colored plate and 309 engravings on wood. Philadelphia: Lea Brothers & Co. 1888.

The Alcohol Habit. By L. W. Baker, M.D., Member American Association for the Cure of Inebriates; Corresponding Member Medico-Legal Society, New York, etc. Baldwinville, Mass. Reprint. St. Louis: 1888.

Stricture of the Urethra; Urethrotomy under Cocaine Anæsthesia. By Henry J. Reynolds, M.D., Professor of Dermatology in the College of Physicians and Surgeons; Professor of Skin and Genito-Urinary Diseases, Chicago Polyclinic, etc. Chicago. Reprint. 1888.

A New Way of Training Nurses. By A. Worcester, A.M., M.D., Fellow of the Massachusetts Medical Society, etc. Boston: Cupples & Hurd. 1888.

Dissolution and Evolution and the Science of Medicine: an attempt to coördinate the summary facts of pathology, and to establish the first principles of treatment. By C. Pitfield Mitchell, M.R.C.S. England, etc. London: Longmans, Green & Co. New York, 1888.

A Manual for Hospital Nurses and Others engaged in Attending on the Sick. By Edward J. Domville, L.R.C.P. London, M.R.C.S., England, etc. Sixth edition. Philadelphia: P. Blakiston, Son & Co. 1888.

The Language of Medicine: A Manual giving the Origin, Etymology, Pronounciation and Meaning of the Technical Terms found in Medical Literature. By F. R. Campbell, A.M., M.D., etc. New York: D. Appleton & Co. 1888.

A CASE OF GENERAL PARALYSIS OF TEN YEARS' DURATION; DEATH FROM HEART DISEASE.[1]

BY G. F. JELLY, M.D.

FORMERLY the duration of general paralysis of the insane was stated to be from two to three years, and the average residence of cases in an insane hospital was nearer two than three years, as the hospital rarely received them till the disease was quite advanced. An earlier recognition of the symptoms has extended the average time, as has been clearly shown by Dr. C. F. Folsom in a recent paper. Much depends upon the acuteness of the observer, and much upon the surroundings of the patient and the care which he receives, nothing being so favorable as a quiet and well-regulated life, and nothing so unfavorable as excitement and confusion. Probably the average duration of the disease in the better class of patients is from four to five years. Cases of much longer duration are known to have existed, but those which have lived nine or ten years are very rare.

The following case is interesting, as showing a fair degree of intelligence after, at least, ten years' duration, through nine of which he was more or less under my observation. For portions of the history of this patient I am indebted to the records of McLean Asylum:

A. G. B. was admitted to the McLean Asylum, May 22, 1875. He was forty-five years of age, a graduate of Harvard College, and a lawyer by profession, whose chief business had been the care of estates and investment of funds for other people, in which he had shown good ability, and had been considered reliable and honest. He had made for himself a competency, and lived freely and rather luxuriously. In early life he had been a private secretary to the historian, Prescott, and was a man of literary tastes, and also well versed in the modern languages. After coming to the Asylum and being put under guardianship, it was found that he had lost much of his property through unwarranted extravagance and foolish purchases, especially through the payment of exorbitant sums of money for land adjoining his home estate, which was in the country, and that his trust accounts were in a state of chaos for a period of from one to two years previous to his commitment. Indeed, could it not have been clearly proved that he had been mentally unsound during that time, he would probably have been arrested by those whose property had suffered. His friends stated that one of his brothers died insane, and that for six years he himself was quite intemperate, but for the six years just previous to 1875 he was temperate, though fond of wine and champagne. They had recognized no disease till about ten weeks prior to his admission to the Asylum, when, while in Boston and very busy, he had some kind of an ill turn, in which he complained of severe pain in the back of his neck, and seemed dazed. He was very restless that night, and the next day was excited and forgetful of the names of his family, and able to see only one-half of an object. Two days afterwards they noticed a staggering gait, thickness of speech, tremor of the hands, and a tendency to talk continually. He improved somewhat for a week, but, finding himself unable to sign a check, became very much excited, was extravagant, talked of his great wealth, wanted everything, and, if refused, was very angry. He finally became abusive and uncontrollable, and was brought to the Asylum. When admitted, he walked with an unsteady and feeble gait, was excited, and there was considerable difficulty in articulating words. He was very angry when he found where he was (his friends had not told him), and made many threats.

May 26th, four days after admission, the record states, he is in a very chaotic state, does not remember the names of people which he has been told within ten minutes, and does not know his own room.

June 1st. Continues about the same, with slight increase of his unfavorable symptoms. Thinks that he goes to walk and sleeps in various rooms, is extravagant, and offers large sums of money for his discharge.

June 20th. There is no improvement. Is becoming filthy.

July 13th. He has had several congestive attacks from vaso-motor disturbance, one of which was very severe, confining him to his bed for several days, and rendering him utterly incoherent and oblivious of passing events. When he rallied, it was found that his memory was much more impaired than it had been.

August 6th. He is somewhat clearer mentally, and there is some physical gain. He is more quiet, though always exhilarated.

August 30th. His ideas of great wealth continue, and he still confuses persons, talks all the time when he can find an audience.

He has four children, but insists that he has six, giving names to the two extra ones, and describing their appearance. He says that he is going home to make their number an even dozen. He is now easily controlled, and his wife removed him from the Asylum a little more than three months after his admission.

He was taken at once to his home. He made search for the two imaginary children, but was soon convinced of their unreality. He gradually became more quiet, and before the end of a year his extravagant delusions concerning his wealth left him, but his exhilaration, his difficulty in articulation, the tremor of his tongue and lips, and his ataxic gait continued. Owing to the ravages he had made in his property, he lost his home, which had been one of affluence, and was reduced to comparative poverty. He moved to Cambridge a year or two after leaving the Asylum, and spent much time in the College library. His memory for past events and for what he read was comparatively good, but for the minor matters of ordinary life it was unreliable. He could, for instance, never do the marketing unless his wife wrote down for him every article needed. He passed much time in translating Italian and Spanish, I understand, with accuracy, and prepared a book of Proverbs which he had translated from the Spanish. During this whole time he became poorer and poorer, but this gave him little or no anxiety. His wife was at work, and he had enough to eat and drink, and could continue his reading and translating. All other things seemed of no importance. He was almost uniformly good-natured and tractable, recognizing in a degree his condition, but hopeful and full of schemes for the future. He was subject to periods of confusion and partial unconsciousness, after which he would be less clear for a time.

[1] Read before the Boston Society for Medical Observation, April 2, 1888.

In 1881, after living in Cambridge three years, he moved to Boston to a poorer home and greater poverty. He and his family would have actually suffered had they not been helped by richer relatives. His children were poorly clothed, his quarters were small, his wife hard at work, but he was complacent and comfortable. He still continued his translations, and some time in 1881 was asked to translate for a lawyer friend a paper relating to an Italian patent. The validity of the patent, as I understand it, turned upon the rendering of a certain word. With his usual self-confidence, he allowed himself to be put upon the witness-stand in the United States Court, bore himself well, and his opinion was sustained. For this service he received ten dollars, which he spoke of to me with great glee, and immediately made many plans to increase his wealth by similar work.

It was then over six years since he had left the Asylum, one year of which he had been very much impaired, and the other five comparatively clear and comfortable. In the early part of 1882 his mental condition became worse. He was more forgetful, less attentive to reading, and more careless in his appearance. He was more subject to periods of dulness and confusion. He now conceived an animosity to his oldest son, a quiet and well-behaved boy of sixteen, and abused him roundly. He began to drink occasionally, a small amount of liquor making him very irritable and quite drunk. He was very penitent after these indulgences, but they were often repeated.

In September, 1882, he came to me and asked to be sent to the Danvers Hospital, giving as his reasons that he was not so well as he had been, that he could not resist drinking, and that his children disturbed him. It was very evident that he was losing mental strength. He seemed to enjoy the process of being committed, especially an interview with the judge of probate, very much. He remained at Danvers two months. On his return, though he was more quiet, his memory had failed, he was often dazed, and frequently lost his way in the street. He had a good deal of difficulty in going down stairs. It was arranged, soon after his discharge from Danvers, that he should go to McLean again, and he was readmitted there November 9, 1882. The certificate of the physicians at this time was:

"He has never been well since he was first discharged. He is in a state of almost constant exhilaration, is sometimes irritable, and easily excited. There is tremor of the lips and tongue, and his gait is impaired."

He remained willingly at the Asylum, spending most of his time in reading, and as was the case while at Danvers, became more quiet under the influence of a regulated life and proper food. He was allowed a good deal of freedom, made several visits home, and was discharged much improved May 1st, after a residence of about six months. From that time till the autumn he continued quiet and comfortable, but there was a deterioration in his mental power and physical strength. He could write very little, his handwriting was sometimes almost illegible, and he read mostly works of a lighter character than formerly.

In October, 1883, he again came to me and wanted to go to the McLean as a place of refuge and quiet, realizing fully that he was losing ground. He was sufficiently clear to be admitted as a voluntary patient, and it was thought best not to go through the formality of a regular commitment. He was received October 23d. I again quote from the Asylum records: "It is thought that he has failed mentally since he was here before, as well as physically. Now he frequently asks his way to his room, and could not go about town alone. He has an idea that he can go into a law office and do clerical work, or may go into a partnership with some one." At the same time, his memory was a good deal impaired and his handwriting was tremulous, and in his letters the words were misspelled or omitted.

These periods of hospital life were always of benefit to him, and he always came away less excitable and in better physical condition.

After leaving the Asylum in December, 1883, he continued to fail mentally and physically. His gait was more enfeebled, his steps were of unequal length, his articulation worse, but he never lost his hope or his confidence in his future prospects. He became less cleanly and more irritable. He could converse intelligently and continued his reading, but in a desultory fashion. It was no longer safe to permit him to go any distance from his home alone.

While in this condition, in the spring of 1884, he suddenly died with symptoms of angina pectoris. He was not in Boston, and I did not see him at the time. The physician who was called detected valvular disease of the heart. Nothing had called my attention to his chest, and I had not examined it for a long time. He had no disease of the kidneys. He had, to my certain knowledge, suffered from general paralysis of the insane for more than ten years.

With the exception of the case of another gentleman, who is still living and in pretty good mental and physical condition, who is also suffering from general paralysis, I have never been able to follow a patient with this disease for so long a time.

The case which I have related seems to me remarkable, not only from the fact that the patient lived so long, but, also, that after a period of utter incoherence and great prostration, he rallied so far that there were four years when the disease was apparently stationary, during which he lived very much as sane and well people do, and that he preserved such a good amount of intelligence and physical strength to the end. I think there is every reason to believe that he would not have died from the effects of general paralysis for some time longer.

During all the years of my acquaintance with him the diagnosis of his disease was unmistakable, and there was no difference of opinion among all the physicians who saw him, who were accustomed to observe similar cases. There was no reason to suspect that he had ever had specific disease. The knee-jerk was always diminished, and latterly, entirely lost. The pupils were sluggish and small, but equal in size.

From the time that I first saw him there was loss of mental power, difficulty in articulation, an unsteady gait, either excitement, extravagance, or a comfortable sense of well-being, even under the most trying circumstances, and, with the exception of the four years in which there was little apparent change, his progress was steadily downwards, with occasional short improvements.

—The International Ophthalmological Congress will be held at Heidelberg, from the 9th to the 12th of August next.

ONE, POSSIBLY TWO, CASES OF GRAVES'S DISEASE.[1]

BY FRANK E. BUNDY, M.D.

I TRUST that you will pardon me if before reporting the two cases which have come under my observation I recall briefly to your minds the symptoms and somewhat of the history of a disease which, by some, has been styled Graves's disease, by others Basedow's disease, according as the writers have regarded the Englishman or the German, the first to group and call attention to these cases, and by others exophthalmic goitre.

The three cardinal symptoms of this disease are palpitation of the heart, enlarged thyroid, and protrusion of the eyeballs, and these occur usually in the order named. A fourth symptom, first pointed out by von Graefe, and regarded by some as almost an essential feature, but which, if I am not mistaken, does not occur in a majority of the cases reported, is a want of harmony between the movements of the eyelids and the eyeballs, by which, on looking downward, the eyelid, instead of following the movements of the eyeball, stops half-way, or on a line with the horizon. Associated with these is a long list of other symptoms, not all occurring in the same subject, but made up from the various cases reported, such as a small, rapid, and often weak pulse, ranging from 80 to 160, sometimes uncountable, strong pulsation of the carotids in the neck, an aneurismal thrill and a bellows-murmur in one, sometimes in both lobes of the thyroid, occasionally organic disease of the heart, tenderness over the region of the cervical sympathetic, emotional disturbances, great irritability of temper, sudden changes from excitement to depression, a mild form of mania, insomnia, loss of appetite, diarrhœa, increased body-heat, elevation of temperature, profuse perspiration, tremor of the hands, partial loss of motility, alteration in the color of the skin, cutaneous eruptions, and, in women, disturbed menstruation.

To fairly come under the head of Graves's disease, a case should show, at least, two of the cardinal symptoms, one of which should be palpitation of the heart. Cases are reported in which the exophthalmos was wanting, others with no enlargement of the thyroid, but none, so far as I know, where the heart was unaffected. One eyeball only may protrude, one lobe of the thyroid be enlarged, and these deformities may occur on the same or on opposite sides.

Of the etiology of the disease not much can be said that is satisfactory. Sex, age, a neurotic disposition and heredity are regarded as predisposing causes. Twice as many women as men have the disease.

The age at which the disease is most common is between fifteen and forty. The cases of a boy at eight and a woman at sixty are on record. In quite a number of cases a history of insanity or nervous disease has been detected in the family. The immediate cause may be some great mental emotion, or overtaxing of the brain, and one case is reported in which the disease developed rapidly, after a severe blow on the head. There seems to be a great diversity of opinion as to the seat of the lesion (if, indeed, there be a lesion) which is the cause of these symptoms.

The number of autopsies is small. Aside from the abnormal conditions found in the orbit and the thyroid gland, the cervical sympathetic and its ganglia seem to be the tissues most frequently found diseased. Dr. Hammond and others claim that it is a disease not of the sympathetic, but of the brain and medulla oblongata.

Just twenty years ago a case was reported to this Society by Dr. Knight, in which an autopsy, made by Dr. Webber, disclosed the sympathetic, with its ganglia more or less altered in appearance, and this corresponds with the results of a majority of the post-mortems made.

The prognosis should be extremely guarded. Some recover, a few are rapidly fatal, others linger on for years, to die of some intercurrent disease.

Of the treatment I shall speak later on. The list of remedies is long, varied, and even contradictory.

My first case is as follows:

On May 16, 1887, I saw at my office, Miss A. E., who called with her mother to consult me with regard to her condition. She was nineteen years old, five feet four inches tall, and weighed about one hundred and forty pounds. In complexion she was brunette, with brown hair and eyes, and was fairly well nourished. She had graduated from the high school in the town where she lived, in June, 1886, and the following September entered Bryant and Stratton's Commercial College in Boston. The school rooms were in an upper story, and reached by four flights of stairs. It was her custom to run up the first three and take the fourth leisurely. She continued in this school six weeks, and was then obliged to give up on account of what her physician called nervous prostration, a prominent symptom of which was palpitation. Later she made two unsuccessful attempts to resume her studies.

From Mrs. E. I learned the following facts. The daughter is an only child, two children having died in early childhood, one from measles, the other from scarlet fever. Both she and her husband are strong and well. Her own father and one sister died with phthisis, also her husband's mother and one sister. In neither her own family nor her husband's is there any record of insanity or nervous disease. She has never regarded A. as a strong girl, and yet never as sickly. She was always of a nervous temperament, easily excited, and subject to severe attacks of palpitation. She began to menstruate when thirteen years old. Until her present illness she had always been regular as to time and quantity of discharge, but with more or less pain. For the last eighteen months the quantity has been diminishing. She was unwell two weeks ago.

There was no perceptible change in A.'s health until some time after she began her school work in Boston. Then her mother noticed that she was becoming restless and unhappy. She could not sleep, and was losing her appetite and strength, and suffering from palpitation and rapid breathing. In December, 1886, about five months before I saw her, the swelling in the neck was detected, and four months later the prominence of the eyeballs was first noticeable. The greatest change was apparent in her disposition. From being pleasant, amiable, easy to influence, she became nervous, exceedingly irritable, hard to manage, and on the slightest provocation very lachrymose. "I know that I am very ugly, mother, but I cannot help it," was an expression she frequently used."

For several weeks she has been having diarrhœa, from three to five discharges daily, small and generally

[1] Read before the Boston Society for Medical Observation, April 5, 1888.

natural in appearance, but occasionally clay colored. Urine normal, except when excessive in quantity and pale. Sleeps badly; is very restless, constantly turning from side to side and throwing off the bed clothes. She complains at times, of great heat and sweating of different parts of the body, especially the hands.

Physical examination: the action of the heart was very rapid and its force much augmented. The impulse could be seen and felt over an increased area of the chest wall. The organ was not enlarged, nor was its rythm irregular; there were no abnormal sounds. The pulse was 140, weak, soft and difficult to count. Both lobes of the thyroid glands were equally enlarged to about an inch in diameter, were soft and yielding and over the right could be distinctly felt the aneurismal thrill, and heard with each systole of the heart the loud bellows-murmur peculiar to this condition. The size of the neck over the thyroid body was 14 inches. The eyes were large and somewhat prominent, the pupils normal; there was no defect of vision. The lids completely covered the eyeballs and the movements of the eyeballs and the eyelids were properly associated. The skin was hot and moist, the temperature was 99⅘. A tremor of the hands was quite noticeable as was also the loss of grasp power. She was unsteady on her feet, and walked as if she had just recovered from a severe sickness.

She was neither anæmic nor chlorotic. She had a severe cough, the result of a cold. She was greatly agitated by the examination and often a flood of tears was the only answer I could get to a very simple question.

I visited A. E. for the second time at her home about twenty-five miles from Boston, June, 18th, and recorded the following: She cannot walk as well as four weeks ago; prominence of the eyeballs is more noticeable; the cough is better; she takes more nourishment; the measure of the neck over the thyroid is 13½ inches, instead of 14 inches; sleeps more but is still very restless; three dejections each day, small and of better color; pulse, 150; temperature above normal.

Under date July 2d, my notes read: There is a decided improvement in general appearance; is more quiet; her mother says, "She is better in her mind." She sleeps well and has no cough; size of neck 13 inches; eyes less prominent.

July 21st. Looks better, less anxious, more cheerful and quiet; size of neck 12½ inches. Since my last visit, three weeks ago, she has lost the power of walking; cannot take a step alone. When lying in bed, she can draw her limbs up or push with them quite forcibly, but cannot lift them perpendicularly from the bed. Sensation but slightly if at all impaired; there is tenderness of the cervical sympathetic at both angles of the jaw. The color of the skin especially of the limbs is a dark brown, almost a bronze. The knee-jerk is absent in both limbs and tickling the soles of the feet elicits no response. The legs and feet are large and heavy; there is some œdema of legs.

From this date, July 21, 1887, to my last visit, February 11, 1888, I saw Miss E. on an average once in three weeks, and in December, 1887, she spent two weeks in town, when I saw her every day, and once in consultation with Dr. Webber.

There has been a slow but steady improvement in all respects except the rapidity of the heart's action. The ability to walk returned gradually. For a long time after she could walk without assistance, she could not get up from the side of the bed or a common chair without help. She now uses a high chair from which she can get to her feet unaided. At the time of my last visit I made the following entry in my note-book: Has gained flesh, eats well, sleeps quietly, ocular prominence hardly noticeable. I find that the size of the thyroid is subject to frequent change. The thrill and bellows-murmur in right lobe of the glands is less marked; pulse 140, temperature 102½, increase of temperature due to a severe cold, from which she is suffering. She is less annoyed by heat of skin and sweat; has walked to a neighbors (about thirty rods away) and back without help, She is decidedly more cheerful, hopeful and amiable; knee-jerk in both limbs preceptible and she responds quickly to the least irritation of the soles of her feet. The color of the skin and the shape of the legs has improved and the little œdema that has existed from time to time has entirely disappeared. She has menstruated twice since last May, the last time ten days ago. With regard to the treatment I would say, that almost every remedy that has been recommended in this disease has been tried faithfully or otherwise. I began with ergot and the bromides, and followed with aconite, belladonna, nux vomica, veratria, several forms of iron, wine of cocoa, and arsenic. Quinine she has taken almost constantly and for the last six months electricity by the faradic or the primary galvanic currents together with massage has been used. The battery employed was the Barrett chloride of zinc battery, one pole placed at the nape of the neck or the angle of the jaw, the other at the epigastrium. It was also applied to the spine and limbs. The strength of the current was what she could bear without great inconvenience.

As I review this case I am persuaded that there is at present no specific for this formidable disease and that benefit has been derived only from those remedies which tend to quiet the nervous system and to aid nature in restoring the general health, and that if Miss E. ever fully recovers, it will be by treatment along this line, and that it will take more than one summer. The moral treatment is as important as the medical. Confidence should be established between patient and physician, all forms of excitement banished, a proper diet, and much out-door exercise prescribed, everything done to inspire hope, and then there should be a patient waiting for the glad fruition. I presume that no one will question the genuineness of the above case.

My possible case of Graves's disease is as follows:

Mrs. Lizzie M., age forty, has been married five years; no children; has never had any uterine disease; is five feet three inches tall, and weighs about one hundred and thirty pounds; complexion fair; father living and well, at seventy years of age; mother died at thirty in childbirth. She has one brother and two sisters living and in good health. Several brothers and sisters died in infancy. One of her father's brothers died insane, and a cousin of her mother is now an inmate of an insane asylum.

Until she was twenty-four she had no sickness except the diseases incident to childhood. At that age she had a severe attack of urticaria, the result, her doctor told her, of eating "moonstruck fish," although two others, who partook more freely of the fish, escaped. For eight years after this attack she frequently noticed in the morning a patch of swollen skin, of

natural color, about the size of a half-dollar, on her forehead or face, and what seemed strange to her was that invariably on the arm, hand, leg or foot, of the opposite side was a patch of skin of the same character. This would last for a few hours and then disappear. With this exception she was well up to 1879, when she became my patient at St. Elizabeth's Hospital, first with typhoid fever, then with pneumonia.

In the fall of 1878 she was engaged in doing general housework in a large city house, and feeling well, was in the habit of going from the bottom to the top of the stairs on the run half a dozen times a day. It was at this time that she began to suffer from severe attacks of palpitation, and that her friends noticed that her eyeballs were bulging out. The ocular prominence continued to increase gradually for about four years, since which time it has remained stationary.

In the winter of 1882–83 she had an attack of erythema of both legs. In August and October, and again in March, 1887, she had attacks of erysipelas of the face.

In the early part of September, 1887, I was called, and found her recovering from what proved to have been pemphigus. It began in her face, and then appeared in the left hand, which was still red, stiff and painful. Before the left hand was well the disease broke out afresh in the right, and from that time until the last of December, nearly four months, she was a great sufferer, and was confined a greater part of the time to her bed. She has not yet fully recovered the use of her right hand, but is slowly improving in her general health. Her eyes are very prominent, so much so as to attract attention on the street. The eyelids fail to cover the eyeballs by at least the eighth of an inch. By gentle pressure the globes can be pushed back, but immediately return when the pressure is removed. There is no want of agreement between the movements of the eyelids and the eyeballs. While there are no physical signs of heart disease, she has frequent attacks of distressing palpitation.

The question, why I regard this case as one of Graves's disease may be very properly asked, and I must confess, that I did not so regard it until the case of Miss E. came under my observation. The immediate cause of the disease seems to have been the same in both cases, and in each the first symptom was palpitation. With Miss E. the other two cardinal symptoms followed in their regular order, but with Mrs. M. the enlarged thyroid was absent, an omission by no means rare. During Mrs. M.'s more recent illness from pemphigus there was a peculiar nervousness, a tremor of the hands, frequent palpitation of the heart, and an unsteady gait, which, to a greater degree, existed in the case of Miss E.

Two cases of undoubted Graves's disease, associated with urticaria, have been reported by Dr. Bulkley, of New York.

Erythema, pemphigus, and urticaria are now classed under skin diseases which may have a neurotic origin.

After preparing this paper I heard incidentally of two other cases of Graves's disease which had never been reported, and wrote to the gentlemen who had them in charge for such information as they could furnish.

The facts are not as complete as I could wish, but are, I think, of sufficient interest to warrant my giving them. Dr. Milton Jay, of Chicago, very kindly sent me what he could recall of the history in the case of Miss R., who died about eleven years ago. His notes, taken at the time, were accidentally destroyed.

She was a school teacher, twenty-four years old, of dark complexion and nervous temperament. Her father died by suicide, insane. One sister was very eccentric.

The immediate cause of the disease was great sorrow, followed by nervous prostration. The symptoms were palpitation, enlarged thyroid, marked protrusion of the eyeballs, the eyelids failing to cover them, a want of harmony between movements of eyeballs and eyelids, increased heat and high temperature, colliquative sweats, great nervous and mental irritability and diarrhœa. During the last two weeks of her life she had peritonitis and metritis, and she died with inflammation of the brain and spinal cord. No autopsy.

I am indebted to the courtesy of Dr. W. Scott Hill, of Augusta, Me., for the following facts in the case of Miss S., who came to him in 1885 as an office patient: She is twenty-nine years old, has brown hair and eyes, nervous temperament, and belongs to a family in which there is no history of insanity, but of which several members have been regarded as extremely nervous. The only known cause of the disease was insomnia, the result of hard study and the excitements incident to social life, her father being United States Consul at a foreign port.

The disease appeared in 1881. She had the best advice that could be obtained abroad, but came home in 1885 with all the principal symptoms well marked. She had palpitation, enlarged thyroid, very large and prominent eyeballs, over which the lids would not meet, and a decided want of agreement in the movements of the eyelids and eyeballs. The pulse ranged from 140 to 150, and she complained of excessive heat, a constant feeling of extreme nervous tension, great restlessness, and loss of sleep. In walking, she had an unsteady, wriggling gait. I know from another source that, as the disease developed, Miss S. experienced that remarkable change of disposition which is almost pathognomonic, and was so prominent a symptom in the case of Miss E. Dr. Hill writes that, after a year's treatment, the thyroid enlargement has entirely disappeared, except what is due to thickening of the tissues, and that his patient regards herself as perfectly well. He attributes the cure to the use of the third decimal tincture trituration of nux vomica. I know that he will pardon me if I suggest that, from my standpoint, more credit should be given to the moral treatment, which I do not doubt he enjoined, than to the much attenuated drug.

Since the meeting of the Society, at which this paper was read, Dr. Frederick W. Johnson has at my request very kindly sent me the following notes of a case in which he was professionally interested: Mrs. E. K., aged forty-seven at time of death, had been married twenty-four years; of dark complexion and nervous temperament. She had been sick ten years. So far as known no history of insanity or neurotic disease in either branch of the family. At the age of twelve she had acute articular rheumatism; never well afterwards, and suffered severely from chronic rheumatic arthritis. The cause in this case is supposed to be heart disease, the result of rheumatism.

The cardinal symptoms were present. The action of the heart was exceedingly violent and the pulse rapid, ranging from normal to 120. There was mitral regurgitation. The thyroid gradually increased

in size, for seven years, and then remained stationary. The protrusion of the eyeballs was very marked for eight years. At times, the lids failed to cover the globes. For some time before death, the lids did not follow the eyeballs on a downward glance. The patient had hysterical paralysis of the œsophagus, numbness of right hand and arm, with inability to use them. She was very irritable, had sudden attacks of dyspnœa, was unable to sleep, on account of restlessness, and at times talked as if greatly confused.

There was increase in the secretion of sweat with cold hands and feet. There was great tremor of the hands and lips. The cause of death was œdema of the lungs, the result of heart disease.

Twice in the course of the disease, when the life of the patient seemed threatened, great benefit was derived from Dr. Weir Mitchell's plan of treatment, a month's rest in bed, frequent feeding, massage and electricity. At one time the action of the heart was reduced from a pulse of 120 to 90 by the use of aconite.

A CASE OF LABOR WITH THREATENING SYMPTOMS.[1]

BY EDWARD REYNOLDS, M.D.

MRS. B., a large and strong woman, with a previous history of exceptionally good health, placed herself under my charge in the sixth month of her second pregnancy. She was at that time very little troubled by the disorders usual to her condition, and a routine examination of the urine detected nothing abnormal. She remained comfortable in every way until about the middle of the eighth month, when she began to complain of a constant pain in the lower abdomen, referred, for the most part, to the symphisis pubis, and due probably to distension from the rapid increase of the uterus, which was already of the size usual at term. Abdominal palpation, made at this time and frequently repeated, established the probable presence of a single, rather large fœtus, and an excess of liquor amnii. Two weeks later (at about eight months) her feet, hands, and eyelids became decidedly œdematous, and remained swollen, though to a varying amount, during the whole of the remainder of her pregnancy.

During the last six weeks she was troubled at different times by frontal headache, disturbed vision, a slight recurrence of the nausea of pregnancy, and by a constant ringing in the ears. The urine, which was examined repeatedly, was light-colored, of low specific gravity (1010-15), and was always passed in very large amount, usually three quarts in the twenty-four hours. It contained a very slight trace of albumen, but no casts were ever found. The patient stated that from early girlhood she had passed habitually a very large amount of urine, and that she thought the present amount was no more than was usual with her.

Treatment consisted of tr. ferri chlor., gtt. xx, t. i. d., regulation of the diet, and general hygienic precautions. The distension steadily increased, and by the end of pregnancy amounted to a distinct, though not excessive hydramnios, but she kept about the house, and was, under the circumstances, very active.

During the ninth month she was twice threatened with premature labor, and on both occasions the cervix was much shortened and the os dilated to the size of a ten-cent piece, by regular and intermittent uterine contractions, but with each attack, rest in bed and the moderate use of opiates resulted in the disappearance of the pains.

True labor set in at 1 A. M., October 26, 1887, and the patient reports that at 4 A. M. the membranes ruptured and a large quantity of water escaped. On my arrival, at 5 A. M., I found her in a state of intense, unintermittent pain, with apparently but slight exacerbations, although examination proved that the uterine contractions were strong and regular and fairly intermittent. The head was high and movable, O. L. A., well flexed. The os was of the size of a dollar, the caput already fairly large. The fœtal heart distant, but regular. The woman, who was usually calm and easy-tempered, was in a state of great excitement and irritability, alternately caressing and scolding her husband and nurse, throwing herself about the bed, screaming, and demanding instant relief. After watching her for a few minutes, I pushed up the head and allowed the gradual escape of about a quart of liquor amnii. The pain almost at once became intermittent, and the patient gradually returned to a more rational mental state.

During the next two hours she behaved well, and the pains were very strong and regular, with good intermissions. Under their influence the head became firmly engaged at the superior strait, but was delayed by bony resistance, and did not as yet bear against the os, which hung away from it, thick and rigid, and still no larger than a dollar. By 8 A. M. the patient was again becoming tired and irritable, and the moderate administration of ether was tried, but as this only increased the excitement, it was carried to the point of surgical anæsthesia for rest. Under ether, the os was soft and dilatable. On recovery from the ether the patient was somewhat more quiet, and at 8.30 A. M. the head made a slight advance and rested against the os, apparently with its greatest diameter just through the superior strait, but in spite of magnificent pains the os remained rigid, and no further advance occurred, while the patient's irritability steadily increased, until she reached a state of almost maniacal excitement, and at 10.30 A. M., during the acme of a pain, a marked twitching of the hands and eyelids was observed.

Ether was at once administered and forceps applied. The extraction of the head was slow and rather difficult, and the size of the shoulders caused a somewhat long delay. The child was a girl, living, $10\frac{1}{16}$ pounds in weight, naked. Its delivery was followed by the escape of about a quart and a half of liquor amnii.

The uterus, though firm, was very large, and a moderate hæmorrhage at once started up. The placenta was extracted manually, and the uterus was found to be in a condition of firm contraction, with but little retraction; that is, the uterine walls were firm and thick, the anterior and posterior walls lying in contact, but the intra-uterine space was more than large enough to contain the expanded hand. Moderate hæmorrhage continued, and a piece of ice was passed into the uterus; but, as this was not expelled, a corrosive douche at about 110° F. was substituted for it, with an equal absence of effect. The uterus was then freely massaged between the hands, one being applied to the abdomen externally, and the

[1] Read before the Obstetrical Society of Boston, April 14, 1888.

other inserted into the posterior cul-de-sac. Under this treatment the uterus slowly and gradually shut down and the hæmorrhage ceased, after lasting about ten minutes, the loss of blood being considerable (perhaps from twelve to fifteen ounces). This condition is rare, and was, I think, undescribed until Matthews Duncan reported a case in the *London Lancet* for October 15, 1887. It is probably associated, as a rule, with previous extreme distension.

The patient recovered from the ether in fair condition, and did thoroughly well till the fourth day, when she became rapidly œdematous, the swelling of the eyelids in especial being so great as to almost close the eyes. She complained of intense frontal headache, and the amount of urine had suddenly fallen from three, to one and one-half quarts in the twenty-four hours. It was rather dark, specific gravity 1020, albumen a trace, no casts detected. The skin was moist and the thirst great.

She was ordered to drink large quantities of water, to take an ounce of Epsom salts in divided doses during the evening, and to promote sweating by warm coverings, and, if necessary, by heaters. During the night she sweat profusely, had ten watery dejections, drank two quarts of water, and passed about a quart of much lighter colored urine, and by morning the headache had disappeared, the œdema was greatly diminished, and she said that she felt well. Free ingestion of water was kept up, and a saline was occasionally administered, and by the seventh day of the puerperium the œdema had disappeared, and the urine had returned to its usual quantity of three quarts, and to its usual light color and low specific gravity.

The remainder of her convalescence was rather slow, and was marked by several slight and transient attacks of œdema, which yielded readily to mild treatment, but at the end of six weeks she appeared perfectly well, and has enjoyed really perfect health from that day to this.

The case seems to me to possess several features of considerable interest. The constant and almost unbearable pain, evidently due to over-distension, and promptly relieved by the escape of a moderate quantity of liquor amnii; the rare and peculiar condition of the uterus post-partum; and finally, the occurrence of marked uræmic symptoms in the presence of a normal and even rather large amount of urine, and this in the case of a woman who is the subject of a habitual and apparently physiological polyuria, with the ready relief afforded by mild treatment, all seem to me to be points well worthy of record.

REPORT ON OBSTETRICS.

BY C. M. GREEN, M.D.

LAPAROTOMY IN EXTRA-UTERINE PREGNANCY.

BREISKY [1] (Vienna) reported a case in November, 1887, which is of great interest as being the only one so far as known, in which, with the child living, the entire fœtal envelopes were successfully removed. The child was asphyxiated, but was resuscitated. The sac was found to proceed from the right broad ligament, from which it was separated by numerous ligatures and removed; it was also attached to the mesocœcum, from which it was peeled off. In extra-uterine pregnancy, the fœtus being dead, Breisky advises against too long postponement of operation, lest the fœtal sac becomes too firmly attached and therefore more difficult to remove.

TRIPLET-LABOR.

Among 14000 deliveries in the Lying-in Hospital of Brussels there have been three cases of triplets. All three children of the first case remain alive: in the second case the delivery was premature (5 months), and the fœtuses macerated. MOERLOOSE [2] now reports a third case, in which the children were born alive, nursed, and were discharged in very satisfactory condition. The diagnosis of triplet-pregnancy was not made. After rupture of the membranes of the first child, the size of the presenting head seeming smaller than would be expected from the size of the uterine tumor, the presence of twins was suspected, and the detection of several large parts confirmed that suspicion. After the birth of the first child, two others were found in the uterus. The first child weighed nearly three pounds, the second four pounds and the third three and one-sixth pounds.

MORPHIA IN PUERPERAL ECLAMPSIA.

G. VEIT [3] (Bonn) recommends the exclusive use of morphia (by subcutaneous injection) in the eclampsia of labor, and ascribes the hitherto inefficiency of the drug to the much too small doses in which it has been given. Beginning with half a grain, one should boldly increase in twenty-four hours up to a grain and a half or even three grains. The apparent success of this treatment, by which during a series of years Veit lost no cases of eclampsia, made him so confident that he announced in his lectures that no one should ever allow a patient to die in eclampsia. But in the last year Veit lost two cases, and he therefore advises in severe cases to make use of hot baths (110° F.) with subsequent wrapping in blankets. Speedy delivery, so far as can be practiced without undue injury to soft parts is always indicated.

[The experience of Veit is interesting, and shows that the morphia treatment, to be successful, must be pursued heroically. It is a fair question, however, how far Veit's success was due to morphia and how far to the "speedy delivery" which he says is always indicated. Certainly speedy delivery under anæsthesia, with subsequent treatment directed to the skin and kidneys, is almost invariably successful; and it is difficult to see how morphia can save a case which does not respond to the above treatment.— REP.]

THE RELATION BETWEEN THE PUERPERAL PSYCHOSES AND PUERPERAL INFECTION.

HANSEN [4] (Copenhagen) has written a monograph on this subject for the purpose of showing that puerperal infection, to which most modern authors ascribe only an occasionally predisposing significance in common with other causes of the puerperal psychoses, possesses a far greater causal importance. During his service as hospital-assistant, partly in the psychiatric, and partly in the obstetric, departments, Hansen collected 49 cases of puerperal psychosis, of which num-

[4] Copenhagen, 1888. Centralblatt für Gynäkologie, 1888, No. 20.

ber he himself observed 21. In these 49 cases there was evidence of puerperal infection in not less than 42; and of these 42 cases not less than 12 terminated fatally. Among the seven cases in which the existence of infection could not be proved, there were two cases of eclampsia with hallucinations of short duration: the remaining five cases were of another nature, pure melancholia, hysterical mania, etc. With the exception of eclampsia the author ascribes to other ætiological factors no great significance, and lays the greatest stress on puerperal infection. The importance of the subject with respect to prophylaxis is evident.

THE EFFECT OF ERGOTIN ON THE INVOLUTION OF THE UTERUS.

BLANC[5] (Lyon), to test the effect of ergotin in promoting the involution of the uterus *post partum*, took a hundred cases of spontaneously delivered women, and divided them into three groups. To one group he gave ergotin for five days, to another group for ten days, and to the third group he gave no ergotin at all: in all cases the uterus was accurately measured every day. As the result of his observations Blanc concludes that the use of ergotin *does not accelerate* the involution of the puerperal uterus.

THE CÆSAREAN OPERATION AND ITS RELATION TO INDUCED PREMATURE LABOR, VERSION AND PERFORATION IN CONTRACTED PELVES.

LEOPOLD (Dresden) and his assistants have published a monograph on this subject,[6] based on the rich material of the Dresden clinic.

In Part I, KORN treats of the induction of labor, and gives the statistics of 45 cases in which labor was induced on account of pelvic contraction. In 35 cases the mothers convalesced without fever; in 9, there was fever for from one to three days; there was one death from sepsis. Korn is of the opinion that in the generally-contracted flat pelvis down to 3 inches in the true conjugate, and in pelves without transverse contraction down to 2.8 inches c. v., the indication is to induce labor, and that in the 32–36 week: if this time has passed, the case is to be left to nature, and, if the natural forces are ineffectual, resort should be had to podalic version and extraction (by forceps if necessary, and failing thus by craniotomy to the after-coming head).

On this last point Löhmann writes at length, from a material of 5,916 cases, in which internal version was performed 107 times. In cases wherein the conjugata vera of the brim does not fall below the measures above given, that is, 3 inches in the justo-minor, and 2.8 inches in the simple flat pelvis, Löhmann advises leaving the case to the natural forces, if the child is of only medium size. If operative interference is found to be necessary, then version, manual extraction, forceps or craniotomy, as may be necessary. If the child is lost by this method of procedure, the next time he would induce premature labor.

PRÄGER reports 71 craniotomies performed in the Dresden clinic within the last four years, and is persuaded that craniotomy performed under rigid asepsis has shown far better results than the antiseptic Cæsarean section.

[5] Lyon Médicale, 1877, August 7. Centralblatt für Gynäkologie, 1888, No. 17.

[6] Stuttgart, 1888. Centralbl. für Gynäkol., 1888, No. 19.

LEOPOLD contributes the section on the Cæsarean operation, and critically describes the 23 cases performed in his clinic in the last four years. He then raises the question whether we are to-day justified in putting this operation before and in place of perforation of the living child, or in what cases this is necessary. He would have it believed that laparotomy is, and must remain, a serious operation, even in the most practised hands: and while it is a great thing to save both mother and child, still if all the conditions of success are not fulfilled, one ought to resort to early perforation. The following table shows the results in Leopold's clinic of each of the methods under consideration:

Operation.	*Maternal Mortality.*
Induced premature labor	2.2 per cent.
Version and extraction	4.8 "
Craniotomy	2.8 "
Cæsarean operation	8.6 "

The mortality from sepsis alone was:

After induced labor	2.2 per cent.
" version and perforation	0.0 "
" perforation	0.0 "
" Cæsarean section	4.3 "

The percentage of living children discharged from the clinic was,—

After induced premature labor	66.6 per cent.
" version and extraction	59. "
" Cæsarean section	87. "

[Leopold's teaching is eminently conservative and will tend to check, it is hoped, a growing *furor operativus* in favor of the Cæsarean operation. Leopold has done much to bring this operation to its present high state of success, and reports a maternal mortality of only 8.6 per cent.; as 4.3 per cent. of fatality is attributable to sepsis, it is probable that this per cent. will be considerably reduced. It should be remembered, however, that Leopold's cases were carefully selected, and operated on in a well-equipped hospital, with all the conditions of success fulfilled. To undertake the operation after long delay, and after futile attempts at delivery by other means is reprehensible, does not deserve success, and seldom attains it. It is the duty of the obstetrician to acquire the art of accurate pelvimetry, and thereby establish the probabilities of success by different operative measures. When cases are seen sufficiently early, the induction of premature labor (with the modern improved methods for the care and feeding of premature infants) holds out gradually increasing prospects of success. In cases not seen until full term, while version and extraction succeed in very many cases of moderate pelvic contraction, the operator occasionally has to choose between the Cæsarean operation and the perforation of a living child. It is proper in such cases to let the patient and her friends decide; but the imperative duty of the medical attendant is *not to lose time;* to recognize early the probabilities of the case and to perform early the elected operation before conditions arise that jeopardize success by any operation. Cæsarean section is not a difficult operation, and if performed *early*, with rigid asepsis, and with accurate uterine suture, it ought to be successful in careful hands in a large per cent. of cases; but, as Leopold points out, it is a serious operation, and should not be undertaken, even by practised hands, unless the patient elect to run a greater risk herself rather than to acquiesce in the destruction of fœtal life. — REP.]

Clinical Memoranda.

A CASE OF PURULENT, PUERPERAL PERITONITIS, SUCCESSFULLY TREATED BY INCISION AND DRAINAGE.

BY SAMUEL B. WOODWARD, M.D., WORCESTER, MASS.

Mrs. M., a young American woman, had a short and easy labor with her second child early in November, 1887. A chill, four or five days later, was the first sign of impending trouble. For several weeks there was continual fever, profuse sweating followed by dryness of the skin and progressive emaciation, and towards the end of that time, abscesses appeared in the lower left arm, all nourishment was vomited, and the general condition became desperate.

Late in the evening of December 7th, she complained of sudden sharp pain in the abdomen, and showed signs of collapse. Dr. T. H. Gage was called in consultation by the attending physician, and on examination found a largely distended abdomen, which was flat on percussion with the exception of narrow spaces in each flank and below the ensiform cartilage. The left side of the abdomen was much larger than the right. Fluctuation was marked, the wave reaching entirely across the belly. Near, and to the left of the umbilicus, was an irregular prominence which suggested the pointing of an abscess.

The lateness of the hour, and the condition of the patient, prevented action at that time, and as Dr. Gage could not attend to the case the next day, he advised that I should be called in to aspirate the abdomen. I therefore saw the woman for the first time the next afternoon.

She was extremely emaciated. The tongue and teeth were covered with sordes. The skin was dry and harsh, and peeling from the body in large sheets (I was shown almost complete casts of the fingers and palm). The odor in the room was something to remember. The pulse was 130, and very weak; the temperature, 103°. The bowels were constipated; a small amount of bloody discharge flowed from the vagina. The uterus was with difficulty reached by the vagina being pushed far forward. Its size could not be determined. There was no marked bulging in the posterior cul-de-sac. The abdomen was irregularly distended, the left side being much more prominent than the right. Flatness on percussion extended over the entire left side, reaching to an imaginary line drawn from the pubes to the ensiform cartilage, about an inch and a-half to the right of the median line. There was no diminution of dulness in the flanks. Fluctuation was marked over the dull area. The right side of the abdomen was abnormally tympanitic with the exception of the flat area above noted near the median line, and another in the right flank. In the region of the cæcum, and along the descending colon could be felt several of the so-called "lymph cakes." There was little or no abdominal tenderness. No nourishment had been retained since the previous day, the patient vomiting at frequent intervals.

Little or nothing was to be gained by aspiration in this state of affairs, and laparotomy was advised. I was obliged to wait until the next day when Dr. Gage could be with me. December 9th, he examined the patient with us, noted the changes that had taken place, and agreed to a moderate incision, to be enlarged if it should seem advisable.

Accordingly, an incision two inches long was made, some four inches above the middle of Poupart's ligament, on the left side, and over three quarts of extremely offensive pus evacuated. As far as possible the operation was made aseptic. The abdomen was scrubbed and disinfected, as were the operator's hands and instruments. All hæmorrhage (which was rather free), was checked before the peritoneum was opened, and the abdominal cavity was washed out with large quantities of a saturated solution (1–1100) of hydronapthol, after which a rubber drainage-tube was carried down, as far as possible, behind the uterus, and the abdomen dressed with bichloride gauze and absorbent cotton.

I was, however, obliged to operate with the patient in bed, where she had been, almost without change, for several weeks, and in a room throughly saturated with septic matter, and was also obliged by her condition to suspend the washing out of the abdomen, while the wash-water was still turbid with pus. That night the temperature was 102.2°, the pulse 120. The dressings, which were saturated with pus, were changed. The patient was too weak to be further disturbed.

December 10th. The temperature was, in the morning, 99.5°. The abdomen was thoroughly washed out with several quarts of boiled water. Estimated amount of pus one pint. The patient had slept well. There had been neither nausea nor vomiting. The evening temperature was 100°; pulse 104. Everything was soaked with purulent fluid. The abdominal cavity was washed out as before.

December 11th. There was a very slight discharge at the morning washing, and about two ounces at night.

For the next five days the abdomen was washed out once daily, the amount of discharge being at the end of that time insignificant. During this time the temperature was normal; the patient began to take nourishment and to gain in strength; Constipation, which had been obstinate was relieved, to be followed by relaxation of the sphincters and involuntary movements.

December 18th. The temperature rose to 100°, and a small abscess was found in the left labium majus, and another in the left lower arm. After these were opened, the temperature fell to normal, and was not again elevated. The tube was retained in place seventeen days, perhaps several days longer than was necessary. The patient is now, five months later, in good health.

Circumscribed collections of pus in the peritoneal cavity after confinement, have been frequently found and successfully evacuated, but rarely after attaining the size here noted, and still more rarely after invasion of the general cavity of the abdomen. This invasion undoubtedly dated from the sudden collapse of Wednesday, and it was not until thirty-six hours later that the operation was performed. Abdominal examination showed so much diminution in the size of the abscess that much purulent matter had evidently escaped into the general cavity, but in the patient's almost moribund condition had probably started up but a subacute inflammation there.

The patient's condition at the time of the operation was so poor, that systematic laparotomy was rejected, and it was only as a last desperate resort that anything was attempted.

AN APPLIANCE TO PREVENT MASTURBATION.

BY EVERETT FLOOD, M.D., BALDWINVILLE, MASS.

ONE patient, a bright youth of seventeen, turned up this year at our Hospital Cottages, who kept himself from masturbation when not asleep, but often awoke to find himself accomplishing the act, much to his chagrin. He was an epileptic, presumably from this excess, which had become fastened upon him four years before. There was no other cause known. He was having thirty or forty seizures some days, the most of them being an ectasis of from ten to forty seconds' duration. He clinched his hands tightly, sometimes raising them above his head, and again pressing them tightly into the bed on which he sat, assumed a broadly smiling expression, but with mouth closed and eyes open, trembled a little just as a person often does as as he finishes a gape raised his feet from the floor a few inches both together, and suddenly resumed consciousness and his natural position.

Under treatment, dietetic and medicinal, he improved; and after his masturbating was entirely ended, the spasms did not recur, and have been absent for nearly three months.

The mechanical appliance used to assist his resolution was a plaster bandage applied as follows: A sheath of oil-silk was first made, to cover the penis and project an inch beyond, the limp organ hanging down straight between the thighs; then a layer of cotton wadding covered in the scrotum and buttocks, leaving a triangular opening, three inches on each side, for defecation. The plaster bandage then covered all, and went down around the penis and up about the waist, making, when hard, a complete casing, so that the boy's genitals might have been in the next county for all the sensation his hands could communicate.

He managed very well at stool, suffered no chafing from the edges between the thighs, walked freely enough (though he could not take full-length steps), and urinated while standing and holding the vessel under the projecting oil-silk. He surely did not masturbate.

He soon acquired a confidence that was comforting, and his self-respect began to improve. After a few weeks he felt tolerably safe; and, as the bandage had become soiled in places, and was rather disagreeable in consequence, it was removed, and has not yet been reapplied.

There seems to be no reason why such cases may not wear a similar appliance any length of time and with perfect protection. The writer trusts that this method, if not already in use or condemned as useless, may prove of service to others.

Therapeutical Memorandum.

ANTIPYRINE AS AN ANALGESIC.

BY EUSTACE L. FISKE, M.D.

FOR the past six months, observations upon the use of antipyrine have been made at the Adams Nervine Asylum.

In twenty-six cases its value as an analgesic or hypnotic has been more or less fully demonstrated. Headaches of a purely neuralgic character have been wholly or in part relieved. Those dependent on digestive disturbances have failed of any noticeable improvement from its use.

Patients with sensation of heat and fulness in the head, flushing of the face, and headaches preceding or attending catamenia, have been benefited.

Of twenty-two cases of headache, eleven were relieved, seven partially, and four not relieved, three of the latter class having but one exhibition of the drug.

Intercostal neuralgias, pain about the joints and heart, have also been relieved. In some patients, antipyrine, by diminishing the intensity of the pain or relieving it, allowed them to sleep, while in others it seemed to directly induce sleep.

One patient, having used morphine before admission for headache, received considerable benefit from antipyrine as a substitute, so that the use of the morphine was wholly given up. Unlike morphine in its after-effects, antipyrine also does not require increasing doses, and in many cases of headache or moderately severe pain nearly as satisfactory results can be obtained, but in extreme cases it is less reliable. No unpleasant effects, like cardiac depression or collapse, have occurred in any case.

Some patients prefer antipyrine to any other remedy, partly because of relief from pain, and partly because of its agreeable effect, one patient enjoying the slight sweating which followed its use.

When first used, ten to fifteen grains in solution were given, and occasionally repeated in a few hours, if needed. Later, fully as good results have been obtained from four or five grains every half-hour till three to five doses are taken, as required. A few patients take it at evening when needed, one in particular every night. Another obtained immunity from pain on two grains, t. i. d., and preferred it to any thing else. No hypodermics were given.

Thus, from the above, we seem to have in antipyrine a partial substitute for morphine in relieving pain without deleterious effects, and one whose action is more or less certain.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

APRIL 14, 1888, the President, DR. WILLIAM L. RICHARDSON, in the chair.

DR. EDWARD REYNOLDS reported

A CASE OF LABOR WITH THREATENING SYMPTOMS.[1]

DR. BOARDMAN pointed out the distinction between contraction and retraction, believing it to be imperfectly understood and appreciated. The patient is not safe from hæmorrhage until the uterus has been reduced to its proper size by retraction of its musculature.

DR. J. C. MUNRO, a guest, raised the query whether the process of retraction may not have been interfered with by an hydræmic infiltration of the uterine muscle. May not a serous infiltration of the uterus exist to such a degree that retraction cannot take place until many contractions of the uterus, in-

[1] See page 30 of the Journal.

duced by massage or otherwise, have expressed the fluid?

Dr. J. P. Reynolds did not see why any distention of the uterus might not make it difficult for retraction to take place, even without any infiltration. He is always impressed by the alarm felt by some men at the rythmical contractions and relaxations of the uterus *post partum:* such phenomena are quite normal and essential to the process of retraction.

Dr. C. P. Putnam, a guest, asked the reader if in this case the uterine wall felt œdematous. The reply was in the negative: the walls felt firm, and the uterus ultimately became hard and globular, and was below the symphysis on the tenth day.

The President asked what symptoms there were of uræmia. The reader replied that œdema of hands and eyelids, frontal headache, return of nausea, changed temperament and vision, and twitching of the eyes and hands when the pains came on certainly suggested that condition.

The President did not recognize œdema as in any way pointing to uræmia. He would not have been concerned at that semblance of symptoms, if the urine was abundant. He had seen cases of convulsions in which the urine was said to be abundant, but had found on catheterizing only a slight amount. He had never seen eclampsia occur when there was any amount of recently secreted urine in the bladder; but it should be remembered when in an eclamptic urine is found in the bladder, that the patient may not have passed water for some time, and that no urine may have been secreted for some hours. Hydramnios is not an uncommon cause of eclampsia from pressure; but the urine always shows some disturbance of the kidney.

Dr. Blake queried whether convulsions might not occur from intensity of pain, with no concomitant uræmic symptoms.

Dr. J. P. Reynolds quoted a case in which the patient had eight convulsions, and yet her urine had been ample. He would not feel easy with such an array of symptoms as the reader's case presented, as the amount of urine might suddenly fail. Moreover, with eclampsia threatening, any sudden shock, even a sharp word, may serve to induce the convulsive seizure.

Dr. Rotch reported

A CASE OF NOMA,

and presented for the inspection of the Society a photograph of the disease taken on the last day of the patient's life.

A girl, aged four years, entered Dr. Rotch's service at the City Hospital, July 5, 1887, with measles. Up to within two weeks of entering the hospital the patient had had an attack of pertussis of rather long duration. When convalescent from the measles, about July 7th, the child began to lose her appetite and to have a cough, which soon developed into an acute catarrhal pneumonia. The urine was reported as normal at this time.

July 24th there was found to be very little improvement in the pneumonia, and the child was very weak and emaciated.

July 25th the right cheek began to swell, and a bad odor to come from the mouth, but nothing especial could be found in the mucous membrane of the buccal cavity.

July 29th the swelling of the cheek had increased, there was œdema of the lips and eyelids, so that the right eye was partially closed: the swelling was semi-fluctuating: the right nostril was apparently closed. The temperature at this time varied from 102 to 103. The cough was much lessened.

July 30th, a bluish-black patch the size of a cent was found at the right corner of the mouth, and this rapidly increased during the day.

August 1st, the dark-colored area had increased considerably in size, and presented a circular outline, with a clearly marked line of demarcation: the child was stupid, and had a profuse greenish diarrhœa.

August 2d. Extreme emaciation and rapid extension of the colored area, which involved the whole of the right cheek, right side of mouth, and right nostril, but no loss of tissue. Died suddenly.

Radical treatment of the case was deemed inadvisable on account of the hopeless condition of the patient at the time when it was possible to make a diagnosis.

In answer to questions from the members, Dr. Rotch stated that the disease was very rare, that it occurred in girls much more frequently than in boys, and was most apt to develop in a moist climate: that it is not known to occur in nurslings: and most frequently is found between the ages of two and twelve: that it was essentially a disease which developed in children reduced by, or convalescent from, severe diseases: that mercury probably had nothing to do with the etiology of true noma: that the disease was almost always unilateral, and was apt to start at the corner of the mouth: finally, that purulent and even gangrenous infiltration of the lungs and a catarrhal condition of the intestines, apparently caused by the offensive discharge in the mouth, and posterior nares, are frequently found.

Dr. Rotch also spoke of the difficulty of making an early differential diagnosis from cases of gangrenous

stomatitis, where, if the case was one of real noma, the actual cautery was indicated at once.

DR. C. P. PUTNAM, a guest, expressed his interest in so rare a case, he never having seen a case in America, nor heard of one in this vicinity. He saw one case in Vienna: in that case the slough dropped out and left a hole in the cheek.

DR. SINCLAIR remembered a case that Dr. Perry had reported thirty years ago, following scarlet fever.

DR. ELLIOT had recently seen a case at the Massachusetts General Hospital: there was a greenish patch on the side of the child's mouth. The patient was in fairly good condition, and was to be operated on. He believed that Dr. R. H. Fitz regarded noma as of parasitic origin.

DR. HENRY JACKSON, a guest, had found reported in Dr. J. B. S. Jackson's cases two cases of noma, both following acute exanthemata.

DR. ABBOT had had one case of noma following measles, in a child under two years of age. The disease began on the gum on the right side, and the child died in a week. It had been thought at the time that the disease was consequent upon mercurial treatment; but there was no other evidence of mercurial poisoning, and he could not believe in such an origin of the affection.

DR. GREEN reported the following case of a

FOREIGN BODY IN THE FEMALE BLADDER SIMULATING STONE.

The patient was a young woman of previous good health, who for some time past had suffered with frequent and painful micturition. There was almost constant pain through the bladder, which was increased by motion, especially in riding, or in walking on uneven surfaces, as in stepping from the sidewalk to a street-crossing. Occasionally particles of gravel were voided, and rarely, minute clots of blood. Examination of the bladder proved very difficult, as the urethra was exquisitely sensitive; but a silver female catheter was passed, and the urine thus obtained found to be alkaline and of strongly ammonical odor. On manipulation the catheter was felt to pass over a gritty mass, which on subsequent bimanual examination appeared to be about the size of a hen's egg. No clink was elicited by the impact of the catheter; but from the symptoms and other facts mentioned, a diagnosis was made of vesical calculus. After some preliminary treatment the patient was etherized and a lithotrite passed into the bladder to crush the suspected stone; but repeated attempts failed to enable the operator to grasp the stone, for on closing the lithotrite it seemed to grasp only the bladder wall, and finally the operation was abandoned. Thorough washing of the bladder, however, brought away much sand and several small pieces of calcareous substance, and it was decided to wash the bladder daily with a solution of boracic acid and await further developments, in the belief that what had been taken for a stone must be one or more masses of calcareous matter adhering to the bladder wall.

For four days the patient was much better, and daily washings continued to bring away gritty particles. The next day, however, the urine was very offensive and contained blood and mucus: the patient was unable to sleep on account of pain and vesical tenesmus. It was then decided to dilate the urethra and explore the bladder with the finger: this being done, the originally suspected stone was found to consist of a soft rubber catheter, coiled up to the size of a hen's egg, and thickly coated with calcareous deposit. This it was which was caught in the lithotrite and gave the sensation of catching the bladder wall. No incontinence followed the dilatation of the urethra, and the patient made a very satisfactory recovery. She denied all knowledge as to how the catheter came to have been left in her bladder, and expressed great indignation that some doctor should have been so unskilful; but from my observation and subsequent knowledge of the patient I have no doubt that the catheter had been used either by herself or by an abortionist for the purpose of interrupting a supposed pregnancy, and had been ignorantly passed into the bladder and lost there.

DR. ELLIOT spoke of a case in which, having dilated the urethra, he had found calcareous masses plastered over the bladder wall, and which he was unable to remove with the finger. He therefore crushed off the masses with the lithotrite, but had great difficulty in washing out the bladder: he finally found that the evacuator was clogged with pieces of twisted paper which proved to be fragments of a paper lamplighter. The lamplighter had evidently been passed into the bladder by the patient and had become the seat of calcareous deposit and subsequently adhered to the bladder wall.

Dr. Elliot suggested that for purposes of digital examination the female bladder should be empty of urine, the finger can then palpate the whole surface. In regard to the use of the lithotrite in such cases, the instrument should be held in a perpendicular position, otherwise it hits the uterus.

In the case alluded to, recovery was speedy, and there was no incontinence: he had used for dilating the urethra, first, Hank's dilators and then the finger.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES P. STRONG, M.D., SECRETARY.

MEETING, April 2, 1888, DR. F. C. SHATTUCK in the Chair.

DR. BUNDY presented a paper upon

TWO CASES OF GRAVES'S DISEASE.[1]

DR. VICKERY expressed his pleasure at hearing the favorable result of these cases as in his experience the prognosis was very unfavorable.

DR. G. L. WALTON said that he quite agreed with Dr. Vickery as to the ultimate prognosis of these cases; they recur in all their severity and at short notice, even when improvement has been continuous and steady. Excitement, or any cause such as tends to bring on neurasthenia and other neuroses, will often overweigh the most painstaking and temporarily successful therapeutic efforts. Still, even temporary improvement in the symptoms is grateful, and sometimes the improvement is persistent enough to almost give promise of permanent relief. We are therefore impelled to make every effort. He was pleased that Dr. Bundy had mentioned electricity as one of the apparently effective means among those employed, for its application had seemed to him very valuable. The

[1] See page 27 of the Journal.

galvanic current, not very strong, nor with long-continued sittings, but regularly and continuously applied, he had found most effective. Rapid changes in the current were to be especially avoided, since these patients were even more susceptible to disagreeable cerebral effects of sudden galvanic shocks than the average patient, resembling in this respect the neurasthenic, who is liable to become dizzy and to suffer from headache after comparatively small doses of galvanism, when applied to the head or sympathetic. In this connection he was glad to notice that Dr. Bundy had laid stress on the neuropathic history, and nervous tendency of these patients. This is a feature of Basedow's disease, liable to be overlooked in making the diagnosis; we look for the rapid pulse, the exophthalmos, and the enlargement of the thyroid, of which not all are in every case present, while the nervous irritability is often, at least, as well-marked a symptom as either of the other three, He remembered a case which he had at first mistaken for neurasthenia: the patient was a thin spare man with an anxious expression, and with quick, almost choreic movements; he complained of sleeplessness, inability to work or think, loss of memory, and general mental irritability and depression. The eyes were not noticeably prominent; the pulse was rapid, 120 to 130, but this did not attract especial attention, as it is not infrequent in neurasthenia, to find such a pulse during the excitement of an examination by a new physician. The enlarged thyroid was discovered later, which changed the diagnosis and modified the treatment materially. This patient showed marked improvement under the use of galvanism. The coincidence of mental irritability and other cerebral symptoms with the thyroid enlargement may throw some light on the pathology of neurasthenia, inasmuch as the thyroid enlargement is manifestly due to vaso-motor disturbance. It seems therefore, that the neurasthenic symptoms may, perhaps, depend on similar disturbances in the brain. It is true that the terms cerebral hyperæmia and anæmia have fallen justly into comparative disuse, but it seems not unreasonable to suppose that a weak and irritable sympathetic may cause functional cerebral disorder by impairing the regularity of blood-supply to the nerve-centres.

Dr. F. C. Shattuck alluded to a case of complete recovery spoken of by Flint, in his "Practice of Medicine," and said that though he had never been so fortunate as to encounter such a favorable result he had seen marked and very gratifying improvement. The constant current applied to the cerebral sympathetic he has seen exert marked effect on the exophthalmos, but of no service for the cardiac symptoms.

Of late, it has been stated by Vigouroux, that an early symptom of Graves's disease is a marked diminution of the resistance of the body to the electrical current; if this observation prove to be correct we shall thus acquire a valuable diagnostic sign of early and improperly-developed cases.

The theory that the pathology of the disease consists in an irritation of the sympathetic, does not seem tenable; while this theory may explain the rapid action of the heart and the prominence of the eyeballs, the dilated vessels of the thyroid gland are indications of a paralysis rather than an irritation by the sympathetic.

The reader spoke of the bruit heard in his case over the thyroid, as systolic at times; in those cases which have come under the observation of the speaker, the murmur has been continuous. It seems probable that a number of cases in which only two of the three cardinal symptoms are present, and those not very strongly marked, escape recognition. A patient recently under observation had suffered for years from recurrent attacks of acute and subacute articular rheumatism, resulting in disease of both the aortic and mitral valves. About a year ago she had an hemiplegic attack, presumably due to embolism, and since then has presented a variety of vaso-motor symptoms. The eye balls are prominent and the innervation of the heart is much more seriously impaired than the condition of the valves and cardiac wall would seem to warrant.

Dr. Jelly referred to the case of a lady of twenty-five, coming from an insane family, who presented typical symptoms, but for the last eight years she has been well; the eyes are still slightly prominent, but the heart gives no trouble and the thyroid is all gone.

Dr. Jelly reported

A CASE OF TETANY; A CASE OF GENERAL PARALYSIS OF TEN YEARS' DURATION; DEATH FROM HEART DISEASE.[2]

Dr. Walton said that he was especially interested in the case of tetany as it showed an analogy between this disease and hysteria. That such an analogy existed was already evident from the character of the convulsions, their approach on mental excitement, their complete disappearance without further sequelæ than the lameness of the muscles affected, and by the manifest absence of organic disease of the central nervous system. The allied nature of the hysterical convulsions and those of tetany, was brought out with striking force, however, in Dr. Jelly's case, by the appearance later, in the same patient, of typical hysterical seizures. The spasms, which were the principal feature in the case, could certainly not, however, be named hysterical, the biting of the tongue alone would almost preclude that diagnosis, to say nothing of the typical contractures, which corresponded perfectly with those of tetany.

PROCEEDINGS OF THE GERMAN MEDICAL SOCIETY OF PHILADELPHIA.

CHARLES L. WEED, SECRETARY.

May 14, 1888, Vice-President Lawrence Wolff in the Chair.

Dr. Carl Seiler read a paper on

HYPERTROPHY OF THE TONSILS.

He opened his remarks by stating that as yet we did not know whether the tonsils performed any physiological function or not, but that the view was prevalent that these organs were residuary, and of no use in the economy. He stated, further, that in the normal condition they were invisible, and became visible only by a hypertrophy of their tissue. This view had lately been forcibly expressed by Dr. Daly, of Pittsburgh, and found a proof in the fact that even when slightly hypertrophied in youth, they usually disappeared at the age of twenty-five or thirty years. They had no connection whatsoever with the genito-urinary apparatus, as had recently been asserted.

[2] See page 25 of the Journal.

After briefly describing the minute anatomy of the tonsil, the lecturer entered upon the subject proper, and said that we could recognize three distinct varieties of hypertrophied tonsils: first, the ordinary soft hypertrophied tonsil, most commonly met with in childhood and early youth, and rarely found in adult age. This variety is characterized by simple enlargement of the tonsillar tissue, with a corresponding increase in the size of the crypts, which latter mostly contain plugs of white, cheesy secretion. This secretion in some cases becomes putrid, and emits an extremely disagreeable odor. This simple hypertrophied tonsil is frequently the seat of periodical, acute inflammation, which may or may not produce parenchymatous suppuration. Coexisting with this chronic tonsillar hypertrophy, we usually find a chronic naso-pharyngeal catarrh, and more or less hypertrophy of the pharyngeal tonsil. These conditions give rise to a variety of symptoms, the most prominent of which are interference with proper vocalization and articulation, insufficient aeration of the blood, gastric disturbances, and frequently, catarrh of the middle ear.

The second variety is the so called scirrhous tonsil, first mentioned by Dr. Jarvis, of New York, which is characterized by a smooth, exterior surface and a hard, cartilaginous feel to the touch of the finger or probe. The crypts are usually not enlarged, and, if so, rarely contain the cheesy secretion. This variety of hypertrophied tonsil is met with usually in young adults, and is rarely, if ever, the seat of acute periodical inflammation. The hardness is imparted to it by a deposit of connective tissue between the cellular elements, and particularly around the bloodvessels, canaliculizing them and thus depriving them of their contractility. They interfere by their presence with vocalization and articulation, and naso-pharyngeal catarrh, as well as chronic laryngeal inflammation, frequently coexist with them.

The third variety may be called the ragged, hypertrophied tonsil, and is nothing but the result of the first variety having been the seat of frequent tonsillar abscesses, which have caused parts of the tissue to slough away, leaving a ragged mass of tonsillar tissue between the faucial pillars. It is usually found in young strumous adults, and is, perhaps, the most dangerous to the general health, inasmuch as it gives lodgment to septic material, and thus in many cases produces chronic septicæmia.

Dr. Seiler then entered into the consideration of the treatment of hypertrophied tonsils, and said that in all cases the offending masses should be removed, but that the method by which this was to be accomplished should be carefully considered and adapted to the requirements of each individual case. All chemical caustics applied to the surface of the tonsil were worse than useless, as their application gave rise to a great deal of pain, and had to be kept up for a considerable length of time to produce any results at all. In the ordinary soft variety, the tonsil was best removed by ablation with the tonsillotome. Care should, however, be taken not to wound the edge of the anterior pillar, because a small branch of the tonsillar artery runs close to this edge, and, when cut, gives rise to hæmorrhage difficult to control. If the anterior pillar is adherent to the tonsil it should be loosened, and if this is not possible, owing to the bands of fibrous tissue connecting the pillar with the tonsil being too strong to be torn, the tonsillotome cannot be used with any degree of safety, and the galvano-cautery knife should be used. After the projecting portion of the tonsil had been ablated, the cut surface should be brushed over with a sixty-grain solution of nitrate of silver to cause contraction of the capillaries and to cover the wound; and any secondary hæmorrhage, which, however, rarely occurred, should be controlled with a strong solution of tannic and gallic acid used as a gargle. The old method of removing the tonsils with the volcellum and bistoury, the lecturer said, was unsafe, as the edge of the anterior pillar, even when not adherent, was too easily wounded by the heel of the knife. Total extirpation and enucleation was also dangerous, besides being unnecessary, except in the extremely rare cases of cancerous growth in the tonsil.

The safest and only applicable method of removing hypertrophied tonsils in cases of ragged tonsil was the galvano-caustic. In applying this method, the galvano-cautery knife should be heated to a bright-red heat, and should then be pressed into the tissue of the tonsil by entering one of the crypts and cutting with it from within outward, so that the eschar resulting from the burn can easily fall off, and does not become impacted in the tissue of the tonsil. This procedure, Dr. Seiler said, did not give rise to any pain, and should be repeated at intervals of a week or ten days, and from four to six applications usually sufficed to reduce the tonsils to a size compatible with health and comfort of the patient. Under no circumstances should any operation for the removal or reduction of hypertrophied tonsils be undertaken while the organ was in a state of acute inflammation. In the case of the ragged tonsil, scraping the tonsillar tissue from the capsule with a sharp curette had been recommended, but this method was not only very bloody, but also painful, and on that account the galvano-cautery was to be preferred.

For the removal of the scirrhous tonsil, Dr. Seiler recommended the Jarvis snare as the best and safest instrument. The steel-wire loop should be laid around the enlarged tonsil, and by turning the screw, should be gradually decreased in size until the portion encircled by the wire was cut off. If done slowly, the operation occasioned very little pain, and time was given for the edges of the rigid vessels to become agglutinated, so that little or no hæmorrhage resulted. The best way, he said, was to start the snaring process and then let the patient turn the screw himself, trusting to him that it was not done too quickly; for the patient would tighten the loop until he felt the pain, and would then stop, to begin again when the pain had ceased. The time occupied in thus removing a scirrhous tonsil was from two to three hours.

DISCUSSION.

DR. MUEHLECK suggested that many of the supposed cases of hæmophilia were cases of scirrhous tonsil, in which the canaliculization of the vessels caused profuse and persistent hæmorrhage after ablation. For this reason he asked the lecturer to definitely state the diagnostic differentiation between the soft and fibrous forms.

DR. VANSANT desired the judgment of Dr. Seiler upon the use of alkalies in acute tonsillitis, especially of sodium bicarbonate and borax. He inquired furthermore whether, after repeated attacks of inflammation, the resulting hypertrophy ever spontaneously disappears. In the matter of diagnosis, it should be

borne in mind, that other tissue changes than simple inflammation and hypertrophy may have their seat in the tonsils. It is a question whether the initial lesion of syphilis would be likely to lead to such error. The cases he had observed presented a mere superficial ulceration without induration. In none of the cases reported by Tchisbriakoff, Peterson, Tomasheosky and Seveki within the past year, was the fact of induration mentioned. He would like to know whether this peculiarity is constant in a lesion in this location.

Dr. Wolf had had considerable success in aborting acute tonsillitis by Dr. Seiler's method; namely, by pencilling with a twenty-five per cent. solution of silver nitrate. The attacks were, however, aborted only when the application was made within the first twenty-four hours. Nevertheless, even a later application was generally successful in preventing suppuration, besides giving great comfort to the patient by reducing the tension and pain.

Dr. Friebis noted the frequent association of tonsillar hypertrophy and otitis media, but was not clear in his mind whether the same is to be attributed to impeded nasal respiration (mouth breathing), or to the septic influences from the crypts, or to mechanical obstruction of the mouth of the Eustachian tube by the swollen gland.

Dr. Miller, in using the cautery knife, had frequently had it stick in the tonsillar tissue, and had caused pain and hæmorrhage by its violent removal. This difficulty was due to a too early shutting off of the current and could easily be avoided. The knife should be hot when applied and removed. He had used the galvano-cautery more often than the guillotine, even in the soft variety, owing to an unconquerable prejudice on the part of the patient against any cutting operation. For the same reason the blade must be heated after it is in the mouth so that the patient may not see it. If both tonsils were treated at one sitting, deglutition would be rendered unnecessarily painful. He treats them, therefore, in alternation, with two sittings per week. He reduces them so that they do not project beyond the pillars, and leaves the rest to cicatricial contraction. A most useful battery for the purpose is that of Dr. Seiler. The method of gouging out the growth with the finger is not only barbarous but dangerous. He would not agree with the lecturer that the tonsils are necessarily in a pathological state when they fill the space between the anterior and posterior pillars, and do not extend beyond them.

Dr. Weed quoted the two cases reported by Croly, of primary sarcoma of the tonsil, in both of which, incisions were made to evacuate the supposed abscess. Such an affection might be mistaken for a hypertrophy even more easily than for quinsy, and the guillotine might evoke a dangerous hæmorrhage. In cases of acute tonsillitis the diagnosis is rendered difficult by the fact that a variety of affections have here their local manifestations. Le Gendre considers the tonsil the site of the initial lesions of scarlatina and diphtheria, and Fraenkel calls attention to other varieties of septic infection from this gland. Le Brun looks upon all tonsillitis as infectious, and regulates his therapeusis accordingly. On the other hand, Frœlich reports a group of cases in some of which the tonsil seems to have been the seat of local lesion, although not the point of original inoculation. The first case was one of so-called follicular tonsillitis followed by a fatal suppurative peritonitis. At the autopsy, Frœlich and his assistant sustained slight wounds with a resulting follicular tonsillitis. A number of the household developed similar symptoms. In addition to the cases quoted by Dr. Vansant, of syphilitic inoculation, are a number collected by Dr. Delavan in the "Annual of the Universal Medical Sciences," just published. There being, therefore, so many varieties of acute tonsillar inflammation, it is idle to vaunt any one remedy as being suited to all cases. The strong solution of nitrate of silver had in the speaker's hands seemed to abort the attacks of recurrent quinsy, or had at least modified the process, but had failed in other forms of inflammation. He was unable to state whether the virtue of the silver salt was in its astringency or in its germicide power. In tonsillotomy for hypertrophy, it is, according to the experiments of Zuckerkandl, impossible to wound the internal carotid without cutting the wall of the pharynx.

Dr. Seiler, in closing the discussion, said that the differentiation between the soft and scirrhous varieties of hypertrophy was easily made by the sense of touch, the former being soft and doughy, while the latter was hard and cartilaginous and never occurs before the age of puberty. He believed that an initial lesion of syphilis upon the tonsil was never indurated. This was owing to a poverty of submucous connective tissue. An early diagnostic sign is glandular involvement at the angle of the jaws. The much vaunted alkaline treatment of acute tonsillitis with bicarbonate of soda or borax, had in his experience given no results greater than a temporary alleviation of the pain. The only abortive treatment with which he had had success, was that mentioned by Dr. Wolff. There is no doubt that hypertrophy of the tonsil does sometimes disappear with the advancing age of the patient. This is due to a physiological atrophy of the glands. The periodical attacks of acute inflammation may be prevented by a proper tonic treatment, attention to hygiene, and particularly by ablutions of the neck and chest morning and night.

Recent Literature.

Organic Analysis: A Manual of the Descriptive and Analytical Chemistry of Certain Carbon Compounds in Common Use. By Albert B. Prescott, Ph. D., M.D., Director of the Chemical Laboratory in the University of Michigan. New York: D. Van Nostrand. 1887.

This volume fully maintains the high standard characteristic of Dr. Prescott's works. The statement in the preface that "for certain common carbon compounds, it has beenunder taken to furnish first, systematic chemical description, and thereupon the methods of analytical procedure, qualitative, quantitative, and for proofs of purity, all with liberal citations of the authorities for convenience of further reading," gives but an inadequate idea of the large amount of valuable material which has been brought together in this volume. The following is a partial list of the subjects and compounds treated by the author:

Alkaloids (general article); Alkaloids of Aconite, Cinchona, Coca; The Midriatic, Opium and Strychnos Alkaloids; Ptomaines; Coloring Materials; Ele-

mentary Organic Analysis; Glycerine; Fats and Oils; Plant Analysis; Phenol; Teas of Commerce; and several important Organic Acids, as Acetic (including vinegar), Tartaric (including baking powders), Salicylic, Tannic Acids, etc. All the subjects are treated at considerable length and in the most thorough manner. The sections on fats and oils, and those on the various alkaloids, are worthy of mention in these respects.

To give some idea of the method of treatment adopted by the author, we insert the following table of contents, taken from the article "Opium Alkaloids." List of alkaloids, with description of those of minor importance; chemical constitution. Morphine, yield in opium; crystalline form and heat reactions of the alkaloid and its salts; physiological effects; solubility of the alkaloid and its salts; color tests and limits of each, precipitations; separation from tissues in cases of poisoning, with limits of recovery and organs of deposition; estimation, gravimetric and volumetric, in opium by the several pharmacopœial and other methods, and in tincture of opium by authorized standards; impurities by the pharmacopœial standards in different countries. Narcotine; Codeine; Apomorphine; description, analysis and tests for purity.

Subjects which have not received such thorough treatment in the text are supplemented by references to the most valuable literature on the subject, for convenience of further reading. The bibliography is in fact a characteristic feature, and is so extensive as to add much to the value of the book. The book is not entirely a compilation, however. There is much in it which is the result of the author's own researches and of his many years of experience.

We realize the difficulty in doing justice to a work of this kind in a brief review. The volume certainly represents a vast amount of labor on the part of the author, and is very creditable to him and a distinctly valuable addition to chemical literature. An exceptionally complete index covering thirteen pages accompanies the book. The publishers deserve a word of commendation. The book is well printed, in large type, and on paper of good quality. W. B. H.

The Pathology, Diagnosis and Treatment of the Diseases of Women. By GRAILLY HEWITT, M.D., London. Edited with notes and additions by H. MARION SIMS, M.D., New York. New York: E. B. Treat, 771 Broadway. 1887.

This is the same book which was published in 1883 by Bermingham & Co. The only changes which can be discovered are that it now appears in three volumes, and has two short additions to the appendix, one describing a pessary, the other a tube for drainage after laparotomy. Even the American editor's preface is identically the same, except that it is dated April, 1886, instead of April, 1883. The reader must, therefore, not expect anything new; but as the book is a standard one, its purchase may be safely recommended. It was noticed in detail at its first appearance, so that nothing need be added now.

Quiz Compends, No. 4. *A Compend of Human Physiology.* By ALBERT P. BRUBAKER, A.M., M.D. Fourth edition, revised and enlarged. Philadelphia: P. Blakiston, Son & Co. 1888. pp. 174.

A "quiz" book which has reached a *fourth* edition doubtless meets a demand among students at least equal to its merits. This particular compend, despite its brevity, is in general fairly exact, and will not seriously mislead those who have drunk freely from some larger and fuller spring of knowledge. We must, however, express the hope that, at no distant day, a newer edition will revise the description of deglutition (p. 27); drop or explain the "pneumic acid" theory of respiration (p. 60), which has long since disappeared from most text-books on physiology outside of Philadelphia; put the formation of urea (p. 75) in its true light, and state more accurately the nervous relations of the sweat secretion. *Kath*electrotonic (p. 90) appears to have escaped the keen eye of the proof-reader.

Druett's Surgeon's Vade-Mecum: A Manual of Modern Surgery. Edited by STANLEY BOYD, F.R.C.S., Eng. Twelfth edition with three hundred and seventy-three wood engravings. Philadelphia: Lea Bros. & Co. 1887.

In its new form this well-known work is enlarged to 985 pages. It has been changed from the last edition so extensively that "scarcely a paragraph of the latter remains unaltered." The chapter on the Eye has been replaced by a short description of the injuries of that organ, by Silcock of "Moorfields." Pathology is more conspicious than in previous editions and a copious index is appended. The chapter on Arteries is more complete than is usual in works of this class, and is quite satisfactory. Seventy-three new cuts have been added, forming an almost complete series illustrating the subject of arterial ligation and representing the wound of operation. Aseptic surgery is advocated but no especial attention is paid to its details except at time of operation. The book is an excellent text-book on general surgery and will prove a valuable one to the student or general practitioner, but a careful perusal fails to show that it possesses any greater value than the best works on this subject now at the disposal of the profession.

The Modern Treatment of Pleurisy and Pneumonia. By G. M. GARLAND, M.D. Being No. 7 of the Physicians' Leisure Library. Detroit: George S. Davis. 103 pp.

The authorship of this brochure is a guarantee that it is well written and doctrinally sound. For the portion which treats of pleurisy we have no word of criticism. Of the forty pages given to pneumonia, only twenty deal with treatment. On page 85 we find: "Cold baths are unquestionably a thing of the past. Even in typhoid fever . . . they have fallen into desuetude." We cannot agree with Dr. Garland here; certainly, as far as typhoid fever is concerned, and if the term cold is inclusive of cool, whole baths have never been very generally used in this country in the treatment of acute febrile disease, and even this limited use was curtailed. We believe that now, however, a slow revival of their use is going on, and that they will be more used in the future. In Europe they have held their place much more firmly than with us. Formerly, they were employed too exclusively with reference to the reduction of febrile temperature, at the door of which all evils were laid.

In so small a book, it would seem to us better not to refer to so many writers, some of whom are by no means authorities. F. C. S.

Guide to the Health-Resorts in Australia, Tasmania, and New Zealand. Edited and compiled by Ludwig Bruck. Centennial edition. The *Australasian Medical Gazette* Office, Sidney. London: Bailliere, Tindall & Cox. 1888. pp. 183.

This cannot fail to be a very useful work to Australasians and to travellers from without. Of course, its practical usefulness to us in this country is small, but it is of considerable interest, nevertheless. We Americans are inclined to think that ours is the country, *par excellence*, of material prosperity and rapid growth. Such a book as this is a reminder of what the Anglo-Saxon race is doing to advance civilization at the antipodes. F. C. S.

A Guide to the Practical Examination of Urine. For the Use of Physicians and Students. By James Tyson, M.D. Sixth edition, revised and corrected, with a colored plate and wood engravings. Philadelphia: P. Blakiston Son & Co. 1888.

This admirable manual is too well known to require an extensive notice. The present edition has been carefully revised and has received a few additions rendered necessary by recent advances in the chemistry of the urine. Previous editions of Prof. Tyson's book have been very favorably received, and we predict for the present one an equally cordial reception. It is without exception the best work of the kind in the English language.

Chemical Analysis of Healthy and Diseased Urine, Qualitative and Quantitative. By T. C. Van Nüys, Professor of Chemistry, Indiana University, with 39 Wood Engravings. Philadelphia: P. Blakiston, Son & Co. 1888.

This book is devoted especially to the chemistry of the urine, including sediment and calculi. The quantitative part is exceptionally complete for a small manual. The preparation of the standard solutions required for quantitative work and the methods for the estimation of the various constituents of the urine are explained very clearly and with unusual attention to detail. The book is in all respects an excellent one, and as a guide to quantitative urinary analysis has no superior among the smaller works on the urine.

The Student's Guide to Diseases of the Eye. By Edward Nettleship, F.R.C.S. Third American from the fourth English Edition, with a chapter on Examination for Color Perception. By William Thomson, M.D., Professor of Ophthalmology in the Jefferson Medical College of Philadelphia. pp. 475. Philadelphia: Lea Bros. & Co. 1887.

This treatise has passed through three editions in this country and four in England and is familiar to most medical students of recent years. It is a most excellent work for the purpose for which it is designed, but in the process of the compression of a large subject into a small space has suffered somewhat, as for instance, when the author entirely omits from his description of Blepharitis any mention of the causative influences of errors of refraction in this disease.

The Refraction of the Eye: A Manual for Students. By Gustavus Hartridge, F.R.C.S., with ninety-six illustrations. Third edition. pp. 240. Philadelphia: P. Blakiston, Son & Co. 1887.

Perhaps the best criticism we can make on this work is that the third edition has been called for within three years of its original publication. For a practical hand-book of refraction for students it is a most excellent work. Some chapters have been partly rewritten for this edition and the chapter on Retinoscopy has been notably improved.

A Practical Treatise on Diseases of the Eye. By Dr. Edouard Meyer, *Prof. à L'école Pratique de la Faculte de Medicine de Paris, etc.* Translated by Freeland Fergus, M.B., Ophthalmic Surgeon, Glasgow Royal Infirmary, etc., with two hundred and sixty-seven illustrations and three colored plates. pp. 647. Philadelphia: P. Blakiston, Son & Co. 1887.

This well-known hand-book of ophthalmology which was first published fifteen years ago, has now for the first time been translated into English. The work has passed through three French and four German editions and has besides been translated into Italian, Spanish, Polish, Russian, and Japanese. This book adds another to the already large number of excellent manuals in the treatment of diseases of the eye. The chapters to be especially commended are perhaps those treating of plastic operations about the lids which are carefully and clearly written and profusely illustrated. The colored plates are reproductions from Liebreich's well-known atlas.

Handbook for Young and Old Opticians. A concise and comprehensive treatise on the theory of the optical trade and its mechanical manipulations. By W. Bohne, Optician, with illustrations. 108 pp. New Orleans, La. 1888.

This book strives to teach the optician the theory and practise of his trade: how to test lenses, cut them, and set them in the frames; how to fit the frames to the face, and to modify the frames according to the use to which they are to be put; how to centre and decentre lenses, etc. Unfortunately, the majority of opticians are sadly in need of just this information. The book is judiciously written and covers its subject very well, and deserves a wide reading among the opticians, as it is the only work of the kind that we have seen. There are several appendices on various topics that could have been omitted without injury to the main work. In one of these the author's picturesque style comes prominently to the front, and affords some diversion after the more serious topics preceding, as the following quotation will show:

"A close observer of the facial expressions of different individuals will find the greatest variety in their delineation, based upon the direction of the axis of vision. In children, this axis is almost constantly parallel, producing the impression of thoughtlessness or of the childish, innocent look. With increasing intelligence, the eyes lose their parallelism by being fixed upon objects of investigation. All the affections of the mind are now manifested by certain motions and positions of the eyes, which become more convergent. The lurking look of the convict on trial, the watchful scrutiny of the over-suspicious, the piercing gaze of anger, the lustful look of the libertine, the rude gaze of the ruffian, and the fearful glare of the maniac, are all modifications of the same act, produced by an increasing convergency of the axis of the eyes."

— An International Congress of Dermatology is to be held in Paris in August, 1889, with Ricord as Honorary President.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 12, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

VISCERAL DISEASE AND INSANITY.

ACCORDING to Spitzka in a recent communication on the subject,[1] diseases of the gastro-intestinal tract and the appended glands bear a far more important part in the causation of insanity than is usually admitted in text books on the subject. The existence of a so-called "sympathetic insanity" was acknowledged by the ancients; some modern authorities have denied it. Spitzka thinks that the reaction against the view held by the ancients has overstepped the bounds of truth. He cites cases where the visceral disorder and the mental state have clearly had the relation of cause and effect. The stomach is responsible for no little mental depression and alienation. There are, says Spitzka, patients in the practice of every physician, who are as bright and cheerful on peptonized milk as they are unhappy, wretched and tired of life, on fried potatoes and pork cutlets. Many a testy hypochondriac has no other discoverable cause for his mental disorder than a protracted gastric catarrh, and his mental state is a veritable barometer of the better or worse condition of his stomach.

The liver, erroneously regarded as related to melancholia by the ancients, sometimes appears to occupy an etiological relation to mental disorder. In a case referred to by De la Mettrie, the only lesion found after death was an hepatic abscess. Cyr, (as quoted by Spitzka), has reported a number of cases where attacks of hepatic colic were followed by a stupor which almost approached a coma in degree, and acute yellow atrophy of the liver is often accompanied by furious delirium.

Diseases of the peritoneum are exceptionally enumerated among the causes of mental disease, and Bergmann and Barry have published cases where such etiological connection seems to have existed.

Instances have been reported in which rectal disease (as hæmorrhoids, cancer, prolapsus), or rectal combined with gastric disease, has produced severe mental symptoms. "In one such case," says Spitzka, "there was abnormal narrowness of the rectum, and a radical cure followed dilatation of both sphincters." "In another, where the ingestion of hard meat infallibly provoked the attacks (of terror with impulsions to suicide), it was observed that very severe seizures were followed by a diarrhœa which the patient had come to regard as critical."

Cases of hysterical anorexia are cited as instances of a peculiar, perverted, mental condition, coming on about puberty, which, if not caused, is, at least, intensified and modified by the state of the stomach. "A patient of this class develops a slight dyspepsia, and rendered morbidly sensitive by the existing predisposition to nervous disease usually present in the families of such patients, and doubly so by pubescence, she contracts a positive dislike for food. Improper food causes distress, the tonics, appetizing cordials, and chalybeates with which a mistaken therapeusis drenches her, aggravate the trouble, and dislike is metamorphosed into a belief that food is injurious. All the patient's energies are devoted to the end of resisting the introduction of food, and the morbid concentration on self ultimately leads to the development of a full-blown delusion that God has forbidden her to eat. Meanwhile, the stomach, originally, perhaps, but very slightly diseased, ceases to present any signs of gastric catarrh, yet the patient does not resume eating, but goes on living for months and months on an occasional sip of water, tea, or broth, and is visited by crowds of the marvel-loving majority as a so-called 'fasting girl.'"

Much interest attaches to the influence of intestinal parasites on insanity. "That these," says Spitzka, "are competent to provoke a variety of nervous troubles, such as chorea, eclampsia, and epilepsy, is well known; but that there are well-established cases in which actual insanity ensued, is ignored by the majority of recent writers. The rapid cure of the mental disorder following the expulsion of the parasites is the significant proof that the etiological assignment was correct."

The clinical characteristic of insanity due to chronic disease of the digestive tract is depression, but this depression has rarely the emotional depth of typical melancholia. The true melancholic, says Spitzka, is horrified at life, the dyspeptic melancholic is disgusted with it.

Another characteristic of the mental disturbance due to visceral disease is its rapid change in remarkable parallelism with the somatic state.

But the operation of visceral disease in the production of mental disease, Spitzka thinks, is extremely limited if not nearly *nil*, in persons of previously sound mental health and sound antecedents. But it plays an important rôle as an exciting cause in many neurasthenic and hereditarily predisposed patients. Proper attention to the somatic disturbance is often, therefore, attended by results which strike the patient as magical. The relief of a gastric catarrh causes the

[1] Medical and Surgical Reporter, June 30, 1888.

disappearance of anxious terrors; a constipation, of morbid fears; the expulsion of worms, of a distressing convulsive or maniacal disaster.

TREATMENT OF CHRONIC DIARRHŒA.

Debove in a recent communication to the Medical Society of the Hospitals, claims great success in the treatment of chronic diarrhœa, especially the tuberculous form, generally so little amenable to therapeutic agents, by silicate of magnesia. This remedy he administers in massive doses, half an ounce to an ounce and a half a day suspended in a quart of milk. As a result of this treatment the diarrhœa disappears completely, and give place to an obstinate constipation.

The silicate of magnesia is known under the name of *talc* or *steatite*. The powder of talc is insoluble, inert, and has not heretofore been supposed to have any medicinal properties whatever. According to Debove, it has sedative properties on the digestive tube similar to those of bismuth, than which it is safer — it promotes the healing of intestinal ulcerations, but seems only to be efficacious by its presence in massive quantities. This substance, Debove says, is readily and rapidly eliminated from the intestines.

MEDICAL NOTES.

— The United States Marine Hospital Service in a bulletin, under date of July 6th, announces, that about the middle of June yellow fever reappeared at Plant City, Florida, and there was one death therefrom, June 22d. Another case in the vicinity, four miles and a half from Plant City, died on the 26th. There have been several mild cases in the village, which contains less than 300 inhabitants, but for the present trains will not stop at Plant City, and it is understood that mails will be delivered at Cork Post Office, five miles west of Plant City. In the meantime, by direction of the Governor, the most active measures are being taken by the president of the county board of health, Dr. J. P. Wall.

— A correspondent writes feelingly to the *New England Medical Journal* of the difference in the facilities for performing operations in city and country. He says: "These men, teaching in the great hospitals here, are great men and great teachers, and far be it from me to take one jot or tittle from their merited honor, but oh, how great are their opportunities! If a big operation is to be done in New York, the surgeon can familiarize himself with the parts by immediate dissection. He is supported by able counsel, aided by trained assistants, and last, but by no means least, he goes into the operation without feeling, if his patient die, he will be looked upon as a sort of semi-murderer; for, if an unfortunate result follow, it is quickly forgotten in the hurry and innumerable death-rate of the great city. But with us, how different! A great emergency arises — a serious operation must be done immediately, and, at best, one can rarely obtain more than one professional assistant. Oft-times the assistant will be a common laborer, the best light obtainable a pine-torch or a kerosene lamp minus a chimney, and with a paucity of instruments, because too poor to buy a complete outfit, the surgeon gropes his way through delicate tissues till the work is done and the life of his patient is saved. I recall to mind now a case of successful laparotomy done for gun-shot wound of the abdomen, and reported at the last meeting of our medical society, in which I am reliably informed the operator had only the assistance of a negro field-hand, and worked solely by the light of a pine-torch."

NEW YORK.

— The Board of Health on the 29th of June, appointed forty-one physicians on the special summer service of the Department, which went into operation on the 5th of July. They are engaged for two months at a salary of $100 per month, and each physician is expected to spend at least eight hours a day in visiting the tenement-houses of his district. This work is under the direction and supervision of Dr. Moreau Morris.

— On the 5th of July, Sanitary Superintendent Day, sent to the Board of Health a list of twelve tenement and lodging-houses on Mulberry Street, which are overcrowded in violation of law requiring that there shall be at least 600 cubic feet for each occupant; and the Board decided to at once notify the lessees of the tenements mentioned to make the requisite reduction of inmates within five days. It is a misdemeanor to violate the provisions of the law against overcrowding, and the offenders may be punished by both fine and imprisonment. The lessees are also liable, in a civil suit, to a fine of $10 per day for each day that the overcrowding continues.

— The fifteenth National Conference of Charities and Corrections commenced its Sessions at Buffalo, on July 5th, when the President's address was delivered by Dr. Charles S. Hoyt, Secretary of the New York State Board of Charities. In it the subject of insanity as related to pauperism received extended attention, under the heads of dependence induced by insanity, the elimination of certain insane poor institutions, and immigration and intemperance as sources of pauperism and crime. He expressed the opinion that European countries had been systematically sending paupers and criminals to America, and as a preventive, recommended the examination of immigrants by our counsels and commercial agents abroad, the revision of the Federal immigration law, and its enforcement to prevent the landing of all such paupers and criminals.

— The faculty of the New York Polyclinic have decided to increase the clinical facilities of this institution by establishing a spacious hospital, immediately connected with the College building. It will be opened for the reception of patients in October next.

Miscellany.

PETTENKOFER AND CHOLERA.

THE *Sanitary Engineer* for July 7th, contains the following excellent criticism on Pettenkofer's last cholera report:

"Under certain conditions of disease, or under the influence of certain drugs, all objects appear to the eye as if seen through yellow or green spectacles. Usually this abnormal vision is only a temporary matter, and soon passes off, but there are cases in which the person never sees colors as others do, and is, therefore, said to be color-blind. It is, of course, not easy to convince a color-blind person that it is his vision that is abnormal, and not other people. The same is the case with regard to other modes of action of nerve-tissue, and especially in mental operations.

"No more striking illustration of this can probably be found than the teachings during the last ten years of Professor von Pettenkofer, of Munich, with regard to the modes of propagation of cholera. Here is a man who has done excellent scientific work, has made elaborate investigations, devised new apparatus, performed complicated and difficult experiments, and is everywhere recognized as a leader in sanitary science, but whose praises, even from his own pupils, are always qualified by the remark: 'But he is cranky about cholera.' He has just published an elaborate review of the epidemiological part of the report of the German Commission on Cholera, from which it appears that his view is the same that it was twenty years ago, that he does not believe that cholera is due to a micro-organism, nor that it is spread by drinking-water, nor that it is any way contagious. His review makes a handsome, large, octavo volume, it is ingenious and interesting, but it is the brief of an advocate who is on the wrong side. . . . It is still best to assume that cholera is spread by a living organism through the discharges of the sick; that when it is epidemic it is usually through an infected water-supply, and that it may be prevented, or its spread in a place stopped, by attending to the prevention of the entrance into a country of persons suffering from the disease, by disinfection of baggage, bedding, excreta, etc., and by special attention to the purity of the water-supply."

PRACTICAL HINTS ABOUT CHILDREN.

DR. JACOBI gives in the *Archives of Pediatrics* the following suggestive hints about the management of children. "Always teach a nurse that a child cannot swallow as long as the spoon is between the teeth; that it is advisable to depress the tongue a brief moment, and withdraw the spoon at once, and that now and then a momentary compression of the nose is a good adjuvant. Syrup will turn sour in warm weather, glycerine and saccharine keep. The taste of quinine is corrected by coffee, chocolate and 'elixir simplex.' Powders must be thoroughly moistened; unless they be so, the powder adhering to the fauces is apt to produce vomiting. Inunctions require a clean surface, and are best made where the epidermis is thin and the net of lymph-ducts very extensive on the inner aspect of the forearm and the thigh. Babies after having taken opiates for some time, demand larger, and sometimes quite large doses to yield a sufficient effect. Febrifuges and cardiac tonics, such as quinia, antipyrin, digitalis, strophanthus, sparteine, convallaria, etc., are tolerated and demanded by infants and children in larger doses than the ages of the patients would appear to justify. Mercurials effect the gums very much less in young than in advanced age. The rectum of the young is straight, the sacrum but little concave, the sphincter ani feeble, and self-control gets developed but gradually; for these reasons a rectal injection is either allowed to flow out or is vehemently expelled. Therefore one which is expected to be retained must not irritate. The blandest and mildest is a solution of six or seven parts of chloride of sodium in a thousand parts of water, which serves as a good vehicle for medicine unless incompatible with the latter. The injection must be made while the child is lying on its side (preferably the left side) not on the belly over the lap of the nurse, for in this position the space inside the narrow infantile pelvis is reduced almost to nothing. In many cases of intense intestinal catarrh, large and hot (104° to 108° F.) enemata will relieve the irritability of the bowels and contribute to recovery. They must be repeated several times daily. When there are many stools, and these complicated with tenesmus, an injection, tepid or hot, must or may be made after every defæcation, and will speedily relieve the tenesmus."

ECTOCARDIA CURED BY A PLASTIC OPERATION.

PROFESSOR LANNELONGUE, of Paris, recently presented to the Académie des Sciences a very remarkable case of deformity of the chest-wall, with ectopia of the heart, which he had dealt with successfully by operation, and which we find described in the *British Medical Journal*, May 26th: The patient was a female child, six days old, well formed in every part, except the thorax. On the front of the chest, over the middle of the sternum, there was a circular ulcer, rather larger than a franc-piece, the base being formed by a yellowish membrane, which appeared to be becoming gangrenous. It was already detached from the edges of the ulcer at several points, and thus only imperfectly closed the aperture into the chest. Each beat of the heart pushed it forwards, and on applying the finger during systole, the hardening of the ventricular walls as they contracted could be distinctly felt. The inner ends of the clavicle articulated below with the first rib, and appeared to be free internally and above: the sternum was entirely wanting between them. This gap in the osseous wall of the chest extended downwards in the middle line, the sternum appearing to be represented on each side only by a narrow strip of bone running downwards and obliquely inwards, and finally joining the corresponding piece below the median ulcer already referred to. The deficiency in the bony chest-wall was, therefore, of the shape of an isoceles triangle, the apex being below at the ensiform cartilage, and the base above at a line joining the inner ends of the two clavicles. The side of the triangle measured four, and the base three centimeters. The circular ulcer was, as it were, inscribed in this triangle. On inspiration, the chest-wall corresponding to the malformed part of the skeleton was drawn in, so that a hollow half-an-inch deep was formed at the upper part; in expiration, on

the other hand, it bulged markedly forward. A few days after the little patient was first seen, the remains of the "obturator" membrane at the bottom of the ulcer disappeared; the pericardium was seen to be entirely wanting; the apex of the heart projected outside the chest, and the whole anterior surface of the ventricles was exposed. The hole in the skin became gradually smaller, owing to the formation of large, fleshy granulations, which pressed on the apex and ventricles of the heart, and it was obvious that immediate surgical interference was necessary to prevent most serious disturbances of the circulation. M. Lannelongue, therefore, made two vertical incisions on each side, one and one-half centimeter to the outer side of the ulcer; the flaps thus formed were sufficiently loosened to allow of their internal edges being brought together over the opening in the chest-wall, where they were fixed by three hair sutures. Only a few drops of blood were lost; the operation was not followed by any constitutional disturbance, and the wound was entirely healed in twenty days. Two months after the operation the child was in perfect health. M. Lannelongue points out that in this way he transformed the case from one of "ectocardia" into one of "subcutaneous ectopia." He thinks it possible that the ectopia, which is at present extrathoracic, may in time, as the heart develops, become intra thoracic. Professor Verneuil, in presenting M. Lannelongue's communication to the Academy, remarked that this was the first time such a procedure had ever been attempted.

OVARIOTOMY AND MARRIAGE.

AT a recent meeting of the British Gynæcological Society the question was discussed by Mr. Lawson Tait and others of the effect on the sexual instinct of the removal of the ovaries and testicles, and of the nubility of persons who have lost those organs, contrary to what might be supposed, that question seems to be not perfectly clear. The *Medical Press and Circular*, commenting on the discussion, says that it has always been assumed in the case both of women and of men — and especially in the latter — that the removal of organs so essential to the carrying out of the sexual act in its integrity, is attended with loss of the desire for a function which no longer admits of being performed properly. The belief, however, is one of those which has been handed down as a tradition and re-edited without being put to the test of experience, an experience which for many reasons is best carried out on a third party. This lapsus Mr. Tait has done something towards rectifying. After diligent search, however, he has only been enabled to discover one adult man whose testicles had both been removed, and in this particular case, it is satisfactory to learn that after a period of depression, both the desire and the ability for sexual intercourse have returned in their plenitude, although even Mr. Tait, probably, would not expect such intercourse to be fertile. As regards women, the prevalence of operation for removal of the ovaries permits of the fullest and most conclusive information. Not only does removal of the appendages not destroy the appetite, but in certain cases it even seemed to increase it, a result possibly less desirable than its abolition. Even when the uterus, as well as the appendages, were removed from virgins, married life does not appear to have been other than satisfactory. The inquiries, however, suggest another question, possibly of more practical interest, and that is as to the legal status, as regards marriage, of women without ovaries and men without testicles. As concerns the latter, the deficiency is one which it would not be easy to conceal or explain, but women may and do marry without the husband being necessarily aware of the hiatus in the anatomical arrangements of his better half. A marriage contracted under such circumstances would from any point of view be immoral, and contrary to public policy, and when one of the parties to the contract is left in ignorance of the facts of the case it becomes a fraud of the most cruel description. Moreover, except with the assistance of the surgeon who was instrumental in removing the superfluous organs, it would be difficult for the outraged husband to prove his case, should he be tempted to resort to the law to relieve him of a mutilated and infertile conjoint. In years gone by the question was one which might well be left to the debating societies to discuss, but in view of the extension which the practice of extirpating ovaries has taken of late years, it becomes one of practical interest. If it be hard on the man to give him a wife minus her appendages, it is adding insult to injury to give him for a wife a woman who has not even a uterus to call her own. Yet Mr. Tait was enabled to record the cases of three young women, wombless and appendageless, who had subsequently reported favorably on the matrimonial condition. Where the operation in the case of either conjoint has been performed subsequently to marriage, no difficulty occurs, since each party to the contract has solemnly consented to accept the other for better or worse, but just as lepers are only permitted to marry *inter se*, so the only fit spouse for the woman without ovaries would be the man without testicles.

THE WEAR AND TEAR OF THE MEDICAL PROFESSION.

AN interesting abstract of the recent report by Dr. J. H. Rauch of Illinois, on "the Wear and Tear of the Medical Profession" is given in *Science*.

The author finds that the previously reported favorable statistics on this point have been largely based on obituaries of the more eminent men who achieved marked professional success, and had reference very largely to city physicians, and of the men who, in the smaller towns, are in a position to select their practice and adjust their labors with some regard to regular hours of sleep, meals and relaxation. Comfortably housed at home, properly protected from the weather when making visits, free from the harrassing cares of the *res angustæ domi*, and beyond the torturing anxiety which too often besets the struggle for practice, — the conditions of life in these cases are undoubtedly favorable to longevity. But these are the fortunate few, who bear no more numerical relation to the rank and file of the profession than the general officers do to the rank and file of an army.

Compared with these biograpical subjects, upon whose length of honorable and successful years is predicated the assertion that the wear and tear of the profession does not prevent its members from attaining a high average longevity — compared with these,

Dr. Rauch has, as the result of an extensive correspondence and systematic record, obtained data which show that the average age at death (in Illinois, at least) is not much over fifty-two years; and that only about eleven instead of thirty-five in every one hundred attain the scriptural limit of threescore years and ten.

An examination of the tables shows, that while the death-rate of physicians in Illinois for the first few years after entering upon the practice of medicine is lower than that of all males in Illinois, and greatly less than that of the whole population of the country at large, it increases beyond that of the former class during the decade from forty to fifty, and is greater than that of the latter class in the next decade.

The obvious inference is, that physicians, on entering practice, form a class of selected lives, since they have an advantage of nearly 3 per cent. as compared with all males at the same ages, — that is, from 24 to 40, — and of over 50 per cent. as compared with the total population, both sexes, at the same ages; this latter great disparity being no doubt largely due to the casualties among women during the child-bearing period. As the wear and tear of practice begins to tell, this advantage is soon lost; so that during the period from 30 to 70 the death-rate of physicians is 8 per cent. greater than that of all males, and during the period from 40 to 70 it is more than 11 per cent. greater than that of both sexes.

An examination of the causes of death reveals the result of the exposure, irregular hours, broken rest, and mental anxiety which are the lot of the average practitioner.

In the grouped causes of death it is seen that consumption, diseases of the respiratory organs (including 91 from pneumonia), and Bright's disease caused 268 deaths, or more than one-fourth of the total. If to these be added a share of the deaths from diseases of the heart, — the *sequelæ* of rheumatism, — a fair estimate may be made of the effect of exposure to the vicissitudes of weather upon the wear and tear of medical life. As a result of mental strain and anxiety, of insufficient, irregular, and interrupted sleep, and similar causes, is the total of deaths from diseases of the brain and nervous system, embracing 43 from various forms of paralysis. In the group of zymotic diseases (enteric fever given separately) there were 5 deaths from diptheria, 1 each from small-pox and yellow-fever, and 8 from traumatic infection (septi cæmia, etc.), all contracted from attendance upon patients.

Less creditable to the *morale* of the profession are the 18 deaths from over-doses of opiates and narcotics, the 7 admitted suicides, and the deaths from alcholism, direct and indirect, — 12 of the former, and at least 8 of the latter. There is this to be said, however, in this connection: that the proportion of mortality from these causes is steadily diminishing; and observation shows that this diminution is largely the result of an amelioration of the conditions, especially of country practice, due to better roads and methods of locomotion, increased comfort in living, and less physical strain upon the practitioner. Ten years ago the resort to stimulants upon exposure to the weather, and under the harsher conditions of practice which then obtained, was much more common than it is to-day. And this is also true of the use of opiates and hypnotics. The practitioner, familiar with their power to temporarily stimulate to further endurance, or to produce sleep when nervous and exhausted, had formerly greater temptation to resort to the use of these agents, always ready to hand.

Correspondence.

ON THORACIC DEFORMITY PRODUCED BY ADENOID GROWTHS IN UPPER PHARYNX.

PARIS, June 15, 1888.

MR. EDITOR,— In my book on "Adenoid Growths of the Nasal Pharynx,"[1] I described a peculiar deformity of the chest originating in early childhood, and I attributed its origin to the existence of these tumors. In such cases the thorax is flattened and the sternal ribs, as well as the inferior part of the sternum, are sunken in, whilst their cartilages on the contrary are bulged outwards. As long ago as in 1828, Dupuytren, and in 1843, Robert, another great French surgeon — had mentioned a very similar deformity of the chest, which both ascribed to hypertrophy of the tonsils, thus committing a very excusable mistake indeed, as these authors have not had any knowledge of the existence of adenoid pharyngeal vegetations. These have indeed been discovered much later, and one of the first cases of growths of this nature has been given in a paper of mine, published in 1865 as well as in the well known publications of Czermak and of Voltalini. A circumstance which renders this error the most comprehensible is the one of adenoid growths generally coexisting with hypertrophical tonsils. Notwithstanding his ignoring the said facts, Dupuytren, with great sagacity, had already noticed a gap in the connection between enlarged tonsils and deformity of the thorax, for he had observed that this and other consequences attributed to the hypertrophy of these glands did not disappear in certain cases after tonsillotomy.

In my above-quoted book, I, the first, revealed the real origin of the said thoracic deformity and I explained it by a theory which may be summed up briefly in the following manner: Adenoid growths begin to form in early childhood. When arrived at a certain size, they fill up the nasal pharynx, close the nose from behind and intercept the passage of air through it. Thus the patient finds himself compelled to change the natural nasal respiration for that through the mouth. However, the children do not adopt the latter mode at once, but take to breathing occasionally through the nose, especially when asleep, and when, therefore, the control of will is wanting. Air under those circumstances not arriving through the nose at all or at least not in sufficient quantity, the action of the diaphragm and of the intercostal muscles during inspiration causes the thorax to sink in, for the atmospheric pressure on its outer walls is then superior to the interior one, and besides the lungs are known to have a natural tendency to contract. It is easy to understand that, under these circumstances, the ribs and the intercostal spaces sink in, but it is more difficult to comprehend the bulging of the costal cartilages. I have explained this phenomenon in the following manner.[2] By the giving way of their two points of insertion, namely, the ribs and the sternum, *these cartilages are compressed laterally* and therefore compelled to vault outwards. Now as the skeleton easily undergoes deformity in early childhood, these alterations finally become lasting.

These remarks cannot well have failed to attract the notice of the profession in England and in America, as my book has been twice translated into English. First a full translation by Dr. Macnaughton Jones (then Professor in Green's University, Ireland, now in London) has appeared in 1879 in the *Medical Press and Circular*. Then my late lamented friend, Dr. James G. Cassells, from Glas-

[1] B. Loewenberg. Les tumeurs adénoïdes du Pharynx nasal, etc., Paris, 1878. Published first in the Gazette des Hôpitaux, and printed separately in 1879.

[2] See transactions of the International Medical Congress, III, 236.

gow, has published an abridged translation in the *Edinburgh Medical Journal* in 1879 (April to August) and he treats this special point (*ibidem* pp. 1100 and 1101). Furthermore, an exhaustive abstract has appeared in the *American Otological Journal* (Vol. I, No. 2, April, 1879).

On a later occasion, I again took up the same subject and entered into further particulars in my introductory address on "Adenoid Growths," delivered at the Seventh International Medical Congress (London, 1881) and reproduced in *extenso* in the transactions of this meeting (Vol. III, pp. 283–290. See this especial point on pp. 285 and 286).

Considering all the preceding facts, I have been rather surprised to find the discovery of the real origin of this deformity attributed to M. Chatellier by Dr. Hooper in a paper "On Adenoid Vegetations in Children," published in this periodical (March 15, 1888). In his inaugural dissertation, "Des tumeurs adénoïdes du Pharynx," (Paris, 1886), Dr. Chatellier when coming to this subject, precisely quotes my remarks on the etiology of the deformity which are anterior by eight years to his pamphlet (see his paper, p. 571).

I am fully convinced that the above-quoted remarks, which largely prove my anterior claims, have been merely overlooked by Dr. Hooper whom I wish to thank, particularly for his kindly sending me his paper. In setting right this point I therefore claim my priority before the profession of the United States where I count so many distinguished friends.

I finally wish to avail myself of this opportunity and just mention that the *cutting forceps* figured in Dr. Hooper's paper (page 12 of the pamphlet) is, in fact, only a slight modification of the one I have described and drawn in 1878 in the *Gazette des Hôpitaux* and in my book in 1879 (page 67). The difference consists merely in the prolongation of the cutting ends, modified first by my learned friend Dr. Woakes, from London, and successfully by others. Respectfully yours, DR. B. LOEWENBERG.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 30, 1888.

Deaths reported 3,051: under five years of age 1,468; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 963, consumption 245, acute lung diseases 141, diarrhœal diseases 668, diphtheria and croup 105, scarlet fever 40, measles 33, typhoid fever 32, whooping-cough 27, malarial fever 25, cerebro-spinal meningitis 21, puerperal fever five, erysipelas four, small-pox three. From measles, New York 23, Baltimore three, Philadelphia, St. Louis, Boston, Pittsburgh, Charleston, Fall River and Lawrence one each. From typhoid fever, Philadelphia 12, Baltimore and Washington four each, New York three, Boston, Pittsburgh and Holyoke two each, Cincinnati, New Orleans and Lawrence one each. From whooping-cough, New York 15, Philadelphia and Boston three each, Baltimore, Cincinnati, New Orleans, Washington, Pittsburgh and Nashville one each. From malarial fever, New York seven, New Orleans five, St. Louis four, Philadelphia three, Baltimore and Charleston two each, Cincinnati and Nashville one each. From cerebro-spinal meningitis, New York six, St. Louis and Washington three each, Boston, Pittsburgh and Springfield two each, Cincinnati, Worcester and Lynn one each. From puerperal fever, St. Louis and Washington two each, Cincinnati one. From erysipelas, New York two, Boston and Haverhill one each. From small-pox, Philadelphia two, New York one.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending June 16th, the death-rate was 16.2. Deaths reported 2,923: infants under one year of age 612; whooping-cough 89, diarrhœa 45, scarlet fever 38, measles 30, diphtheria 25, fevers 19, small-pox (Preston six, Sheffield and Hull two each, Bristol, Manchester and Leeds one each), 13.

The death-rates ranged from 9.9 in Birkenhead to 27.9 in Manchester: Birmingham 14.0; Bradford 17.5; Halifax 23.4; Hull 17.0; Leeds 18.0; Leicester 10.7; Liverpool 15.7; London 14.2; Nottingham 19.4; Portsmouth 16.8; Sheffield 15.6.

In Edinburgh 19.7; Glasgow 24.0; Dublin 24.7.

The meteorological record for the week ending June 30, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, June 30, 1888.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

AN EPIDEMIC OF TYPHOID FEVER DUE TO INFECTED MILK.

BY CHARLES HARRINGTON, M. D.
Instructor in Hygiene and Assistant in Chemistry in the Harvard Medical School.

THE epidemic about to be described occurred in November and December, 1886, in the city of Cambridge, Mass., and was investigated by Dr. Alfred F. Holt, for the Board of Health of that city, and by Dr. Henry Jackson and myself, on behalf of the State Board of Health, shortly after the outbreak. The results of our investigations at that time were reported to the State Board, and an account of the epidemic was read by me at the February meeting of the Boston Society of Medical Sciences, but publication in this form has been deferred until now with the hope that further examination might yield additional facts regarding the cause. For the account of the epidemic as it occurred, I wish to acknowledge my indebtedness to Dr. Holt, who made the preliminary inquiry.

Up to the middle of November, there was no more than the usual amount of typhoid in the city; but, beginning on the 18th, the number of cases reported to the local Board of Health was so large as to occasion considerable surprise. Between November 18th and December 2d, sixty-three cases were reported, an average of more than four per day; between December 2d and 31st, ten more were reported, making seventy-three in all. These cases were not confined to a limited area, but were widely scattered here and there throughout that portion of the city known as the Port. It was naturally supposed that the unusual number of cases must have to a certain extent a common cause, but a consideration of the various supposed causes of such outbreaks failed at first to throw any light upon the subject. The water-supply being the same for the whole city, it could hardly be looked upon as the cause of an epidemic confined chiefly to one section. The sewerage also was manifestly not at fault. The probability of infected milk as a carrier of the disease was regarded as very small owing to the fact that the territory invaded was much larger than is usually supplied by a single milk-route.

On making a house-to-house inquiry, however, it was learned that in spite of the wideness of the affected area most of the cases occurred among the patrons of a particular milk-man. Fifty-eight of the seventy-three cases occurred in thirty-six families who obtained their milk from this source. It was also learned that most of these cases were of persons who were in the habit of drinking uncooked milk. The cases which occurred outside this milk-route were not much in excess of the number usually occurring at that time of the year.

It was learned on inquiry as to the source of the milk supplied by this man, that it came through one of the large contractors from five farms in Suncook and Hooksett, N. H. Samples of the milk from each of these farms were taken from the milk-car on its arrival, and were examined chemically for adulteration by addition of water. The analyses made by the writer showed no adulteration, but, of course, this examination could throw no light on the character of previous consignments, though it is fair to suppose that as the farmers were in ignorance of the intended examinations of that particular day, the quality of the milk was about as usual. It was then thought advisable that the five farms should be inspected, and on behalf of the State Board of Health, Dr. Jackson and myself, accompanied by Inspector Terry, visited them on January 4th, to make the necessary examinations. Samples of the milk and of the water-supply of each farm were taken for chemical and biological examination; the results of these examinations will be found tabulated below.

The first farm visited was that of a Mr. Howe. Here were found sixteen cows in good condition, housed in a fairly good barn, which, with the other outbuildings, were in good order. The water-supply was running water conducted through an iron pipe from a spring seventy-five rods away. There was no history of sickness among the family or help. At the Morgan farm the stock and buildings were in good condition. The pump was in the barn cellar, which was to a considerable extent covered with cow-manure. Several head of stock were loosely confined in this cellar. There was no history of sickness. At the Sullivan farm everything was found to be clean and carefully kept. The water comes from a spring in the woods a hundred rods distant, through an iron pipe. At the Whittemore farm the cows looked thin and in poor condition. The cow-stable and other outbuildings did not appear well-kept, and there was a general air of slovenliness about the whole place. The water-supply comes from a well, situated between the house and a graveyard, about eighty feet from the latter, from which there is a slight downward slope.

At the Mann farm the livestock and buildings were found in excellent condition. The water for barn and dwelling was derived from a well twenty-six feet deep, well bricked and curbed, and was conveyed by a lead pipe to a pump in the barn about six feet from the privy vault. The latter was well built of brick and cement seemed quite tight, and there was no odor or perceptible leakage. The lead pipe passed from the pump directly by the vault a few feet below the surface of the cellar floor, to the bottom of the well. The distance between the vault and the well was not more than eighteen feet, but the vault was built up from the cellar-floor and not sunk below the surface.

Our inquiries as to present or past sickness at the farm were answered in the negative. On leaving the farm, however, we received an intimation from a neighboring farmer of whom we made inquiries, that there had been some sickness there in the autumn. The farm was therefore revisited, and the investigation renewed.

On re-examination, Mr. Mann recollected that his son had not felt well in the early autumn, and that on September 13th, he went to bed with typhoid fever. The description of the symptoms was sufficiently convincing that the diagnosis of the attending physician was correct. The father took entire charge of the nursing, and emptied the excreta every day into the vault, and with each addition threw in a quantity of ashes or ordinary soil. At the same time he performed his usual duties about the farm, superintended the milking, and prepared the milk for the market. The sickness lasted several weeks, and convalescence was rapid. The boy was up and about after the first of November, after a sickness of about seven weeks. He had been living at the farm only a month before taking to his bed. On or about November 1st, a man

who had been employed about the farm went away, and about three weeks later was taken with the same disease. A few days after his departure, Mr. Mann assisted by his younger son cleared out the vault, the contents of which were thrown out on the ground near by and covered with earth. On November 18th, that is to say, within three weeks, the epidemic broke out in Cambridge.

The results of the chemical analysis of the samples of water from the five farms are tabulated below.

[Figures express parts per 100,000.]

FARM.	Free Ammonia.	Alb'd Ammonia.	Chlorine.	Residue.			Hardness.
				Fixed	Vola.	Total	
Howe { (running) / { water) }	0.0006	0.0118	0.25	1.3	1.6	2.9	1°
Sullivan, "	none.	0.0034	0.20	3.1	0.9	4.0	1.5°
Morgan (well).....	0.0044	0.0020	1.65	4.5	2.3	6.8	2°
Whittemore (well)	0.0004	0.0026	0.20	2.7	1.2	3.9	1°
Mann, "	none.	0.0046	1.60	6.5	2.2	8.7	4.5°

All five samples were clear, colorless, and odorless, and by the ferrous-sulphate test showed no nitrates.

The chemical examination of the samples showed them to be with one exception waters of unusual purity. The exception was the water of the Howe farm, which showed a rather large amount of albuminoid ammonia, doubtless due to vegetable matter.

There was no chemical evidence of soakage into the Mann well. At the time the vault was cleaned the ground was frozen, and the excreta would therefore have had some difficulty in penetrating through the soil into the well. Any serious pollution in November would probably have left some traces at this time. It seemed advisable to take samples from this well later on, after the frost should have left the ground, and this was done as will be shown.

The biological examination of the samples of water and of milk from the five farms was made by Dr. Henry Jackson, on January 5th, with the following results, which I have been kindly permitted to take from his report to the Board of Health.

HOWE FARM.

Water. 250 to 300 colonies in one cubic centimeter. The following varieties were distinguished: (*a*) Elevated brown colonies of vigorous growth, microscopically, round cocci. (*b*) Rapidly growing colonies, causing liquefaction of the gelatine, and formation of a white flocculent sediment; microscopically, thick, very short rods. (*c*) Elevated fine white colonies causing no liquefaction of gelatine; thick rods about twice as long as they are broad.

Milk. In one cubic centimeter of sample taken from a cool room in the house were found by estimation 2,000 colonies. (*a*) Raised brown colonies; cocci. (*b*) White colonies liquifying gelatine; microscopically, short rods.

Remarks. Bacteria in water more numerous than they should be in good potable water. Before condemning the water, however, two facts must be considered: (1) The water in the trough is constantly open to contamination from outside sources (cows drinking, etc.). (2) Twenty-four hours elapsed before the cultures were made.

WHITTEMORE FARM.

Water. In one cubic centimeter nine colonies: (*a*) Brown, elevated; cocci. (*b*) White, not much elevated, non-liquifying; short, thick rods.

Milk. In one cubic centimeter 100 colonies, mostly the same variety. Microscopic examination of several showed small, round cocci; a few brown colonies; microscopically, cocci.

MORGAN FARM.

Water. In one cubic centimeter, fourteen small colonies: (*a*) Several pure white colonies; microscopically, small, perfectly round cocci. (*b*) Yellowish-white colonies; microscopically, thick rods about twice as long as broad; after a week, slow liquefaction of gelatine.

Milk. In one cubic centimeter, many hundred small, white colonies, and a few brown colonies. (*a*) White colonies, minute round cocci. (*b*) Brown colonies, rather large, oval cocci.

Water contains a small number of bacteria, and in winter at any rate is not contaminated by the overlying excrement.

SULLIVAN FARM.

Water. In one cubic centimeter, forty colonies. (*a*) Chiefly, raised brown colonies; microscopically, short, thick rods. (*b*) A few small, white colonies; cocci. Considering the exposure of the water to external contamination, the specimen contained very few bacteria.

Milk. In one cubic centimeter thirty non-liquefying white colonies; cocci.

MANN FARM.

Water. In one cubic centimeter forty-eight colonies. (*a*) Nine small colonies liquefying the gelatine, and making a white flocculent sediment; microscopically, short, thick rods. (*b*) Thirteen small, white colonies with slight depression of surrounding gelatine; microscopically, short, thick rods. The water cannot be considered as bad.

Milk. In one cubic centimeter about one thousand small, white colonies; microscopically, cocci, many arranged in pairs as diplococci.

Dr. Jackson sums up as follows: "(*a*) No bacteria have been found that can be considered as pathogenetic. (*b*) So far as the number of bacteria determines the quality of the water — that from the Whittemore and Morgan farms is good, being practically free from bacteria; that from the Mann and Sullivan farms cannot be considered to contain an undue number of bacteria; that from the Howe farm is probably contaminated, from some source, with organic matter. The milk from the Sullivan and Whittemore farms contained comparatively few bacteria; that from the other farms a large number, but the examination gives no ground for the supposition that pathogenetic forms are present."

It will be noticed that the biological analysis yielded results in close agreement with those of the chemical examination, and that the only specimen of water to which any exception could be taken was shown by both processes to be probably contaminated by vegetable matter. As indicating any connection between the water-supply and the outbreak at Cambridge, the analyses were perfectly negative. Had the water on the Mann farm, where the sickness had occurred, proved chemically or biologically bad, it might have been looked upon as a valuable piece of evidence in support of the drinking-water theory of the origin or

dissemination of typhoid, and the evidence would have been so much the stronger from the fact that the excreta had been thrown out on the ground some time before the outbreak occurred. At the same time it is to be remembered that the ground was frozen, that the excreta soon became so, and that the well is protected by a curbing from surface-washing. It is possible that the character of the water may have been very different in November from what it was on January 4th, but even a moderate contamination at that time would probably not have disappeared so completely in so short an interval. It is very unfortunate that we have no means of knowing anything about its quality before the outbreak. But assuming that there was a serious contamination in November, how could it have been brought about? Soakage from the vault directly through the soil seems highly improbable on several grounds. The vault was evidently built with great care; the walls are very thick, the floor of brick with eighteen inches of cement; there was no visible evidence of soakage anywhere about the vault, which, being built directly up from the floor of the cellar, was open to ready inspection; moreover, the contents of the vault were at no time in a fluid condition since enough soil and ashes had been thrown in to render the contents at best only semi-fluid. Contamination by the excreta after their removal from the vault and deposition on the ground seems more probable, though as already stated there were some obstacles in the way of that process.

Moreover, the farm-hand who was taken sick at or about the same time that the outbreak occurred in Cambridge, left the farm several days before the vault was cleaned, so that if his case and those at Cambridge had a common origin, that influence was at work before the soil about the well was polluted by the vault contents. That the cause of the outbreak in Cambridge was in the milk supplied from Suncook there can be little doubt, and that the milk derived its infection from the case of sickness at the farm or from the cause of that sickness, seems extremely probable. But the manner of infection is unknown; it may have been through the water, but there is nothing to prove such a condition, and there are reasons already mentioned against it; it may have been through the air, or communicated by the hands of the milkers; or it may have been from the cattle themselves. The theory of cattle origin of typhoid is one not yet fully developed, but very worthy of serious consideration.

As the analysis of the water had given only negative results, and as we had no previous analysis with which to make comparisons, it was deemed advisable to obtain a second sample of the Mann water later on in the season when the frost should have left the ground. It was reasonably supposed that if the well had been seriously contaminated in November, the amount of chlorine at least would be not materially greater in the following May than in January, for had the ground become saturated with the contents of the vault to such an extent that the water in the well could be contaminated, the pollution would under the usual conditions be a continuous one, with after a time, a progressive diminution in amount until the water should again be in its natural condition, provided no new element of contamination were introduced. On the other hand if, as seemed probable, the soil surrounding the well had not become impregnated by the filth, the ground being frozen at the time the deposit of fæcal matter occurred, and the filth itself being frozen, the character of the water ought to undergo considerable change before the end of spring. On May 9th, Inspector Terry again visited the Mann farm, and obtained another sample of water, which he delivered to me immediately on his return. A sample was taken also for biological analysis, and delivered to Dr. Gardner T. Swarts. By chemical analysis I found the organic matter not materially changed in amount, as shown by the albuminoid ammonia. The chlorine and residue, however, were found to have increased very largely, as may be seen from the following figures of the examinations in January and May.

DATE.	Free Ammonia.	Alb'd Ammonia.	Chlorine.	Residue.			Hardness.	Nitrates.
				Fixed	Vola.	Total		
Jan. 4....	none.	0.0046	1.60	6.5	2.2	8.7	4.5°	absent.
May 9....	none.	0.0026	5.80	18.0	6.1	24.1		trace.

From these it will be seen that while the organic matter shows no increase in amount, probably because of oxidation, the chlorine and residue are increased; the former to more than three times its former amount, the latter to a somewhat less extent. In the January sample no nitrates were found by the ferrous-sulphate test, while in the May sample, the reaction was marked.

The biological examination by Dr. Swarts, to whom I am indebted for the report, yielded the following results:

(1) One cubic centimeter gave 1040 colonies.

(2) One-sixth cubic centimeter gave 325, 1950 for the whole cubic centimeter.

(3) and (4) Both plates liquefied.

Isolation analysis: Large, white non-liquefying, irregular; small, white non-liquefying, regular. Fluorescent green liquefying, regular. Growth of white on potato, negative.

In November I communicated with Mr. Mann and requested him to send me a third sample for further comparison, which for some reason he failed to do. Later on, in May of the present year, I sent a man to the farm and obtained a sample, which, compared with the specimen of the previous May, showed a marked diminution in the amounts of chlorine and residue, but yet by no means as great a diminution as was to be expected if no new source of soil pollution had been introduced. No biological analysis was made.

DATE.	Free Ammonia.	Alb'd Ammonia.	Chlorine.	Residue.			Nitrates by Ferrous Sulphates.
				Fixed	Vola.	Total	
May, 1887...	none.	0.0026	5.80	18.0	6.1	24.1	trace.
May, 1888...	0.0024	0.0038	4.14	11.5	4.1	15.6	trace.

The chemical analyses indicated first, that the water six weeks after the outbreak showed no evidence of pollution by the material thrown out from the vault on to the ground near the well; second, that later when the ground was open, a considerable pollution was manifest; and third, that at a corresponding time of the next year, and under the same conditions, the evidence of contamination was not so great, showing an improvement in the character of the surrounding

soil in spite of a possible removal of the cause of pollution.

The possibility of the infection of milk by organisms floating in the air is one which has been long recognized. Direct contamination by the hands of the milkers has been in several investigations of this nature regarded as more than a possible cause. The possibility of animal origin of typhoid fever has been within a few years the subject of careful inquiry, and several investigations of milk typhoid epidemics have given important evidence bearing on this point, which it seems to me is worthy of the most careful research.

The manner of the infection of this particular milk-supply can of course never be known, but in view of the evidence yielded by the examinations of the water, it seems not improbable that contamination was brought about in one of the other ways above mentioned.

ENDEMIC CEREBRO-SPINAL MENINGITIS.[1]

BY CHARLES W. TOWNSEND, M.D.

MEDICAL literature abounds in records of epidemics of cerebro-spinal meningitis, which, first definitely recognized and described in 1805, in Europe, gained a foothold in this country in 1806, under the name of spotted fever, appearing first in Medfield, Mass. Since then there have been numerous epidemics of this disease in widely separated regions of this country, one occurring in Boston, in 1873. But like diphtheria, besides coming at intervals in epidemics, cerebro-spinal meningitis occurs with more or less frequency in certain places at all times, that is to say, it has in these places become naturalized or endemic.

According to J. Lewis Smith,[2] cerebro-spinal meningitis is becoming more rapidly naturalized in the northern than in the southern cities, especially in Chicago, New York, Philadelphia and Jersey City, and that it also occurs, but to a less extent, in Cincinnati, Boston, Worcester, New Haven, Albany, Milwaukee, Baltimore, St. Louis, Minneapolis, San Francisco and other cities. Since the great epidemic in New York of 1872, cerebro-spinal meningitis has not been absent from that city. Smith [3] says that it is fully established there and that "it has become one of the scourges of childhood, destroying many lives each year and injuring irreparably by deafness or in other ways, many who recover." The deaths from this disease in New York in 1883, were two hundred and twenty-three in number, averaging eighteen a month, and very evenly distributed throughout the year, and the fatality has been almost the same for the last few years, the cases all being endemic.

In Boston a few cases are said to have occurred in 1810, at the time of the epidemic in Worcester County. From an examination of the city registrar's reports, first published in 1849, I can find no record of a death by this disease prior to 1865, in which year two deaths are reported under the name of spotted fever. In 1866 there were no deaths, while in 1867, seven deaths are recorded from cerebro-spinal fever. The following table shows the number of deaths in Boston from that date to the present time:

1865	2	1871	3	1877	24
1866	0	1872	60	1878	19
1867	7	1873	216	1879	15
1868	8	1874	35	1880	9
1869	7	1875	41	1881	16
1870	5	1876	13	1882	24
				Total	602.

1883	23
1884	26
1885	19
1886	14
1887	16

An examination of the monthly records since 1879 shows that the deaths are fairly evenly distributed throughout the year, as is shown in the following table of one hundred and sixty-two cases:

January	15	July	13
February	13	August	12
March	26	September	9
April	17	October	10
May	14	November	8
June	13	December	12

Of these cases ninety-two were males, seventy females, and ninety-two were children under five years of age.

The United States mortality statistics for the year 1880, show 2,898 deaths from cerebro-spinal meningitis, of which the larger number 1,537 were male, the smaller, 1,361, female. Nearly one-fourth part of the whole number, or 619, were under one year of age, and 1,567 or more than a half, were under five years. Of the remainder, 761, or over a quarter of the whole number, were between the ages of five and twenty years, leaving less than one-quarter of the whole number of deaths from the disease in individuals over twenty years of age.

The following table obtained at the office of the Boston Board of Health gives the number of deaths from cerebro-spinal meningitis in some of the cities of the world during the year 1885, and is of interest as showing the wide distribution of the disease.

New York	202	London	..
Philadelphia	87	Scotland	..
Chicago	142	Dublin and Cork	..
Baltimore	24	Stockholm	2
St. Louis	30	Belgium	..
Boston	19	France	..

Toledo	10	Danzig	14
Cambridge	1	Prague	3
Syracuse	17	Calcutta	..
Knoxville, Tenn.	5	Melbourne	..
Richmond, Ind.	2	Halifax	..

Cerebro-spinal meningitis, therefore, although but recently recognized, has spread throughout the northern civilized world, and has become thoroughly established, naturalized or endemic, in many of the cities, and we may reasonably conclude that since the disease has been increasing in past years, it may continue to do so in the future. It is certainly important, therefore, to be able to recognize the disease, and if possible, to prevent its spread.

That cerebro-spinal meningitis is an infectious disease, is evident from its course, and from its epidemic and endemic character; that it is not contagious in the ordinary sense of the term is also a well-recognized fact. As is the case with all infectious diseases micro-organisms are generally admitted to be the cause. There are numerous investigations on this point by

Klebs,[4] Fraenkel,[5] Eberth,[6] Leyden,[7] Senger,[8] Weichselbaum,[9] Goldschmidt,[10] and others, even a brief review of which would far exceed the bounds and purpose of this paper. Suffice it to say, however, that there is tolerable agreement among these investigators, in admitting the presence of a micro-coccus in the purulent fluid of the cerebral and spinal meninges found in cases of cerebro-spinal meningitis. Fraenkel found that this micro-coccus was identical with that previously found by him in cases of acute lobar or croupous pneumonia, and this has been confirmed by other observers. Weichselbaum, by injecting pure cultivations of these organisms produced apparently croupous pneumonia or cerebro-spinal meningitis dependent on the place of injection. He also described a second distinct species of micro-organism present in six uncomplicated cases of cerebro-spinal meningitis, named by him *Diplococcus intracellularis meningitidis*, a diplococcus found partly in the pus cells and partly free. Goldschmidt,[11] in a recent elaborate paper, confirmed these observations of Weichselbaum, and with him agreed that in certain cases of cerebro-spinal meningitis, this organism bears a causative relation to the disease. Between croupous pneumonia and cerebro-spinal meningitis there certainly seems to be some relation from clinical observations alone, for the coincidence of the two diseases in the same patient is not uncommon. Dr. Webber,[12] in his Boylston Prize Essay on "Cerebro-Spinal Meningitis," makes a special division for this class of cases where the "force," as he expresses it, "falls upon the lungs" (*vide* also Wilcox.[13])

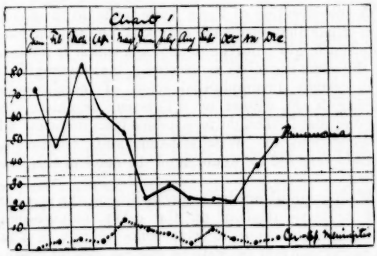
The micro-coccus in producing the disease is supposed to obtain access to the meninges of the brain through the ethmoid plate from the nose in some cases, and from the tympanitic cavity in others, and, as proof of this theory, the organisms have been found by several observers in both of these regions. Although undoubtedly the same organism bears a close relation to both croupous pneumonia and cerebro-spinal meningitis in some cases, yet it seems hardly creditable that ordinary croupous pneumonia, universally common, should be caused by the same microbe as the latter disease, which, unknown in some places, is everywhere rare in comparison with pneumonia. It has been said, however, that pneumonia is much more frequent simply because the micro-cocci have much more easy access to the lungs than to the brain. If that be the fact, then, there should be a tolerably constant relation between the numbers of the two diseases, and, therefore, when pneumonia is very common we should expect more cases of cerebro-spinal meningitis than usual, and on the other hand in epidemics of cerebro-spinal meningitis, pneumonia would rage still more. J. Lewis Smith[14] says that in New York City, during the cerebro-spinal meningitis epidemic of 1872, pneumonia was also unusually prevalent, and the symptoms were of greater gravity than usual. Muscular pains, restlessness, and delirium often preceded for hours or even days the pneumonia symptoms, and in some cases both diseases were developed. In Boston, however, the mortality statistics show no increase of pneumonia during the years of the cerebro-spinal epidemic, as will be seen by a glance at this table.

Year.	Deaths from Cerebro-Spinal Meningitis.	Deaths from Pneumonia.	Percentage of deaths from Pneumonia to total mortality.
1870	5	336	5.51
1871	3	345	5.86
1872	60	517	6.39
1873	216	463	5.88
1874	35	571	7.31
1875	41	632	7.06
1876	13	523	6.38
1877.	24	484	6.64
1878	19	581	7.57

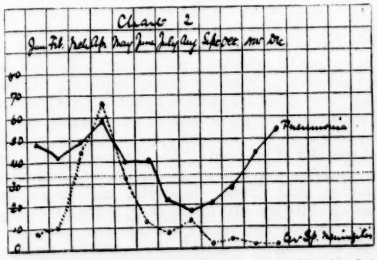
The yearly average ratio[15] of the deaths from pneumonia in Boston to the total mortality from the year 1836 to 1877, is 6.11.

J. Lewis Smith[16] says that from February 1st to June 1st, 1872, when the epidemic of cerebro-spinal meningitis was at its height in New York, 1,707 deaths were recorded from diseases of the respiratory organs exclusive of phthisis, while only 1,336 deaths from the same causes occurred during the remaining eight months.

To show the relations by months of these two diseases in Boston, I have constructed the following charts.



Monthly Mortality from Pneumonia (517 cases) and Cerebro-Spinal Meningitis (60 cases) in Boston in 1872.



Monthly Mortality from Pneumonia (463 cases) and Cerebro-Spinal Meningitis (216 cases) in Boston in 1873.

In 1872 there is no correspondence between the charts of the two diseases, while in 1873 the greater

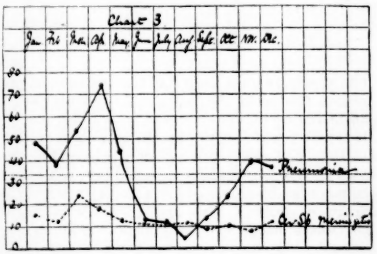
[16] Loc. cit.,

number of cases of both diseases occurred between February and June, thus agreeing with the results found by Smith in New York. This correspondence in 1872 seems, however, to have been accidental as far as the cerebro-spinal meningitis is concerned, as will be seen by reference to Chart 3. Here the pneumonia monthly line represents 412 cases occurring at the Massachusetts General Hospital [17] from 1870 to 1885 inclusive, and it is interesting to see how closely it corresponds with the pneumonia lines on the other two charts. The cerebro-spinal meningitis line represents 162 cases of deaths from that disease in Boston, from 1879 to 1887 inclusive.



Monthly Chart of Cases of Pneumonia at the Massachusetts General Hospital (412 cases) from 1870 to 1885 inclusive, and Monthly Mortality from Cerebro-Spinal Meningitis (162 cases) in Boston from 1879 to 1887 inclusive.

A consideration of these facts tends to the conclusion either that ordinary croupous pneumonia has a different origin from the pneumonia which is produced by the same organism as cerebro-spinal meningitis, or that certain uncomplicated cases of cerebro-spinal meningitis are caused by a different organism from the one that is thought to produce both diseases. The investigations of Weichselbaum and Goldschmidt already referred to would tend to confirm this latter view.

With acute ulcerative endocarditis on the one hand and acute rheumatism on the other, cerebro-spinal meningitis also seems to have some relation as shown by bacteriological as well as clinical studies. Much however, remains to be done to clear up this interesting and perplexing subject.

The diagnosis of cerebro-spinal meningitis, is very simple in many cases where the disease appears in its fully developed form, with characters so distinct that they cannot be mistaken; particularly is this the case in epidemics. Sporadic cases, however, although often very characteristic are sometimes very obscure to the physician, particularly from the fact that he may not be on the look-out for this disease, and does not consider it in making his diagnosis. A typical case includes the following symptoms: rapid onset, vomiting, chill, intense headache, stiffness and contraction of the muscles of the neck, pulling the occiput back towards the spine; opisthotonos, pain in the neck and back, which with the headache comes and goes abruptly; contraction of muscles of extremities, delirium, convulsions, coma; hyperæsthesia of the skin, herpes of face or elsewhere, and occasionally other lesions of the skin in the form of petechial and larger ecchymoses, roseola or erythema, together with an irregular, elevated temperature. The symptoms of Kernig, that is to say, the spasmodic contraction of the flexors of the legs on flexing the thigh on the pelvis, can nearly always be obtained in cases of cerebro-spinal meningitis. It is not, however, diagnostic of this disease as it has been found in purulent or tubercular meningitis or other diseases of the brain and its meninges.

It is a disease which, both in times of epidemics, and when occurring sporadically, may run a violent course, ending in death within twenty-four hours, the shortest case on record being one of death in three and one-half hours, reported by Jewell.[18] This is fulminant cerebro-spinal meningitis, the *foudroyante* form of the French. Secondly, it may appear as the abortive form, with slight or moderately severe headache, stiffness of the neck, and perhaps a few herpes vesicles, and end in recovery in a few days. Thirdly, the so-called intermittent form. This latter form, a a form recently described by Henoch [19] as occurring in Berlin, is characterized by intermissions at irregular intervals, when not only is the temperature normal, but the other symptoms may almost entirely disappear. Thus a child in good health is suddenly seized with vomiting, pain in the head, fever, and rigid drawing back of the head, so that in some cases the occiput may even touch the back. The pain in the head is often severe, spoken of by older patients as boring and intense beyond description, and the child constantly screams and tosses about the bed. Pain in the neck and back may also be present, and the pain is occasionally referred to the epigastric region, as in cases of dorsal caries. Cutaneous hyperæsthesia may or may not exist, and is difficult to determine in children. The other symptoms previously mentioned may also be present. In the course of one or two weeks the fever abates, and with it the other symptoms, and the prospect of speedy convalescence brings joy to the family. The temperature remains normal, the appetite returns, but usually a slight stiffness of the neck muscles exists. After an interval of one or several days, an attack similar to the initial one takes place, with elevation of the temperature, which again lasts for a longer or shorter period. In this way, with exacerbations and remissions or intermissions, the disease may last for weeks. Sometimes the patient sinks into a typhoidal condition, and Hirsch makes a fourth group of typhoid cerebro-spinal meningitis.

All these forms are found both in epidemics and in the naturalized cases, but, according to J. Lewis Smith,[20] the latter are accompanied by less profound blood changes; out of a considerable number of endemic cases observed by him in the last ten years, he has not seen any with ecchymoses, which are so common in some epidemics, and from which the name of "spotted fever" is derived.

In making the differential diagnosis of this disease from others, fulminant cases are generally easily recognized by their characteristic symptoms and their intensity; but in those that terminate within a few hours in death the diagnosis may be very uncertain. Cases of cerebral or meningeal hæmorrhage, with convulsions, rapidly ending in death, may simulate cerebro-spinal meningitis, and, according to J. Lewis

[20] N. Y. Med. Rec., Nov. 24, 1883.

Smith, cases are sometimes called infantile cerebral paralysis. In both these cases the absence of much elevation of the temperature and the evidence of localized cerebral disturbance would be of help in making the diagnosis.

From tubercular meningitis the diagnosis can generally be made, although this is sometimes difficult, or even impossible. The gradual onset of tubercular meningitis, as distinguished from the abrupt onset of cerebro-spinal meningitis, the family history of tuberculosis, and the evidence of a deposit of tubercles elsewhere in the body, are of importance in making the diagnosis. It is necessary to remark here that prodromal symptoms of chilliness, fever, headache, and vomiting may sometimes precede for several days the onset of cerebro-spinal meningitis. Retraction of the head is seen in some cases of basilar tubercular meningitis, but is rarely as marked and persistent as in cerebro-spinal meningitis. If, however, the tubercles have, also, a spinal distribution, as well as cerebral, the symptoms of cerebro-spinal meningitis are necessarily exactly reproduced. In the tuberculous forms, however, herpes or the other skin lesions described above do not occur.

In simple meningitis we have the history of traumatism or of disease of the middle ear to aid us in making the diagnosis. True cases of cerebro-spinal meningitis have, however, been said to follow a blow on the head, or where the brain has been disturbed by strong emotions, as grief or anxiety. Jaffé [21] relates a case where, after fracture of the skull from a fall, vomiting, stiffness of the neck, and convulsions occurred, with death on the third day. The autopsy showed cerebro-spinal meningitis.

The onset of an acute disease in children, like scarlet fever or lobar pneumonia, may be marked by severe cerebral symptoms, vomiting, retraction of the head, convulsions, stupor, together with high temperature, and may lead one to suspect cerebro-spinal meningitis, and it is necessary to reserve the diagnosis and watch the progress of the case. In scarlet fever, the redness of the throat, the existence of an epidemic of the disease, the history of exposure, and later, the appearance of the characteristic rash, makes the diagnosis plain. There are cases of scarlet fever, however, where death occurs within twenty-four hours without the appearance of the rash, and with symptoms very similar to fulminant cerebro-spinal meningitis. In these cases, Dr. Mason [22] remarks that even an autopsy might not settle the diagnosis.

In lobar pneumonia, the frequent absence in children of the cardinal symptoms found in the adult — chill, rusty expectoration, pain near the nipple, and even, in some cases, of cough, with often a delay of several days in the appearance of the signs in the lung — makes the diagnosis obscure. Although vomiting, delirium, drowsiness, and one or two convulsions often occur in these cases of simple pneumonia, if we find persistent retraction of the head, arching of the fontanelle, severe headache, and retardation of the respiration, with frequently recurring convulsions and coma, together with the signs in the lungs, the existence of both cerebro-spinal meningitis and pneumonia is probable. An irregular and intermittent rapid pulse in the pneumonia of children, as well as in other febrile diseases of children, is not uncommon, but, according to Holt,[23] a slow, irregular, or intermittent pulse may be found in meningitis, but not in pneumonia. The persistent high temperature, with little difference between morning and evening, is characteristic of pneumonia, but not of meningitis. Ziemssen,[24] however, says that the temperature and respirations of pneumonia may continue unchanged, notwithstanding the presence of cerebro-spinal meningitis.

From typhus fever, with which cerebro-spinal meningitis was formerly confused, it can be distinguished by several marked features. Typhus fever is highly contagious; the patient does not, as a rule, take to the bed until the second or third day. A copious macular eruption appears generally on the fourth or fifth day. Intense headache and pain in the back, with retraction of the head and opisthotonos, are rarely found in typhus fever. The gradual onset of typhoid fever, together with the abdominal symptoms, make the differential diagnosis in this case clear. J. Lewis Smith relates the case of an infant with a temperature of 104°, stiffness of the neck, and some retraction of the head, which led him to consider cerebro-spinal meningitis, but a more careful examination showed a retro-pharyngeal abscess and beginning cervical caries.

The diagnosis of abortive cases is often only conjectural. Thus, during the prevalence of the disease, cases are frequently observed of lassitude, pain in the nape of neck and in the head, with slight retraction of the head in some cases, and recovery in a few days. Such cases are occasionally seen when no epidemic prevails, but one would hardly be justified in making the diagnosis of cerebro-spinal meningitis unless undoubted cases existed in the same place at the same time. Thus a breast-fed child five months old was seen by me November 29, 1886, who for three days vomited occasionally, nursed but little, cried as if in pain, and drew the head back rigidly, so that the occiput at times touched the spine. The head was kept in this position only part of the time. The fontanelle was arched and the temperature moderately elevated. Complete recovery followed. In a second case, aged fifteen months, where the parents had already made the diagnosis of "water on the brain," similar symptoms lasted five days, and were followed by complete recovery. During an epidemic, these cases might be called abortive cases of cerebro-spinal meningitis; at other times, simple examples of the great reflex nervous irritability in children resulting from insignificant causes.

A temporary pain and stiffness of the neck muscles may be caused by muscular rheumatism. In these cases, which West speaks of, there is an absence of headache, and recovery takes place in a few days, and is aided by warm or counter-irritant applications.

The prognosis in cerebro-spinal meningitis varies extremely, and the mortality is stated at from twenty to seventy-five per cent, but many very severe cases recover. Smith says that "patients who live till the close of the second week without serious complications will probably recover," the danger after this period being mostly from malnutrition and exhaustion. Henoch [25] states that the prognosis is very favorable in the naturalized, intermittent cases observed by him in Berlin; he has never seen a death during an exac-

[25] Loc. cit.

erbation or relapse. Kernig[26] reports a case that lasted two and a half months, and finally died of marasmus, and Larrabie[27] one that died in a similar way at the end of sixteen weeks. Smith reports one that died in eighteen weeks, and another, a boy four and a half years old, whose head was retracted for four and a half months, who became greatly emaciated, and who was unable to get out of bed for five and a half months, but finally completely recovered.

For treatment, opium, often in large doses, is necessary to relieve the agonizing and exhausting pain; bromides are occasionally sufficient; cold applications to the head and spine and a careful sustaining diet, with the use of stimulants in protracted cases, are indicated.

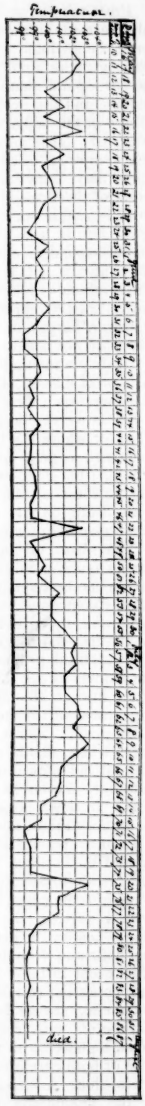
The following two cases illustrate very well two forms of the disease, the fulminant and the intermittent. The first I saw with Dr. F. M. Briggs, to whom I am indebted for allowing me to report the case. The diagnosis in the second case was confirmed by Dr. Rotch and Dr. Buckingham, who saw the case with me:

CASE I. Male, aged two months, breast-fed; previously well. After three days of fever and great fretfulness, the head was drawn back so that the occiput nearly touched the spine, and the infant had several slight general convulsions. When seen at this time, the head was rigidly retracted, the eyes open and staring, the pupils reacting sluggishly to light. Fontanelle arched. Redness and swelling of the joints of fingers and toes, which was marked at first, had nearly disappeared. No eruption on the skin. Abdomen distended and tympanitic; legs rigidly drawn up. Child died two days later without developing any other symptoms. The swelling of the joints is especially interesting, and has been noted by several observers in epidemic cases of cerebro-spinal meningitis.[28]

CASE II. Joseph X., aged four and one-half years, first seen May 16, 1887, and the following history obtained from the mother. Family history good; previously well with the exception of measles when one year old. He began suddenly to vomit on May 9th, at 5 P. M., the vomiting continuing at intervals for two days. From the first he complained of severe pain in the head and abdomen. From the second day the head was rigidly drawn back, and although rational most of the time he had occasionally been mildly delirious. From the first had been feverish; no cough; no convulsions; bowels moved to-day for the first time for a week. Hot applications to the abdomen had given no relief from the pain.

Examination showed a pale, fairly nourished boy, with brown-coated tongue; pulse 124, regular; temperature 102°; respirations 20, regular. Head drawn back so as nearly to touch the spine, the muscles of the neck being rigidly contracted. Slight opisthotonos. No contractions of muscles of limbs. The symptom of Kernig was present markedly. No tenderness along the spine; cutaneous sensibility everywhere normal; no cutaneous eruptions or ecchymoses. Pupils regular, react equally to light; no strabismus or photophobia. Nothing abnormal on thoracic or abdominal examination. Patient tossing about the bed moaning and crying out; expression that of great pain.

He was put on a milk diet and pot. bromide ordered every two hours. As this gave no relief to the intense suffering, morphia, in doses of one-thirty-second of a grain was given. This was repeated by the mother so frequently that the child had one-fourth of a grain in three hours, at the end of which time he fell asleep to awake in eight hours crying out with pain in his head. Ice to head and spine gave no relief, but morphia, to the amount of one-sixth to one-third of a grain during the twenty-four hours, controlled the pain and quieted the restlessness which was fast wearing out the nurse as well as the patient. On the 24th day of the disease the temperature, which had varied between 100° and 103° (*vide* chart), sank to normal, where it remained till the forty-seventh day. During this interval the head was but slightly retracted and the patient seemed to be generally free from pain, but remained in a very listless condition, not speaking, taking but little nourishment and stimulant, becoming emaciated, passing urine and faces involuntarily, and vomiting occasionally. Nutritive enemata were not retained after a few days' trial, buton the 41st day peptonized milk was retained by the stomach, and on the 46th day he improved so much as to take gruel with readiness, and talked and laughed. On the 47th day, June 22d, a relapse occurred, the temperature going up to 103.6°, the head was rigidly drawn back, the eyes were staring, and pain was present. The symptoms of Kernig which had never entirely disappeared, again became well-marked. On the 66th day convulsive movements of left arm and leg with turning in of left eye occurred. Several days previous to this relapse, a numerous crop of sudamina appeared on neck and trunk, and a fugitive erythema and macular eruption on neck and face, lasting only a few hours. From the 61st to the 66th day his body was covered with a macular eruption, the macules varying in size from a pin-head to a pea. At no time were ecchymoses to be seen.



[26] Berlin Klin. Wochenschr., 1884, No. 52.

[27] Richmond Jour. of Med., Dec., 1872, p. 779.

[28] Since this paper was written, I have had a fulminant case of cerebro-spinal meningitis in a female infant of four and one-half months, fatal in twenty-four hours, beginning suddenly with vomiting and high fever, which reached 106°. In the last twelve hours the skin was spotted with ecchymoses, and frequent, irregular, convulsive movements occurred.

Repeated examinations of chest and abdomen showed nothing abnormal.

From the 71st to the 73d day the temperature was again normal, nourishment was taken well, the neck was straight, and general appearances were encouraging, but on the 74th day he again had convulsive movements, most marked on the left side of the body, the head was again drawn back, and at noon the next day his temperature was 103°. The pulse, which during the entire illness ranged from 120 to 140, and had previously been regular, was now at times irregular and intermittent. The bowels were generally constipated. After this, although the temperature came down to normal, he failed rapidly, and on August 1st, the end of the third month or the 87th day of the disease, when he was so emaciated that the finger and thumb could easily encircle his thigh, he quietly died.

A CASE OF CEREBRO-SPINAL MENINGITIS.[1]

BY HENRY B. JACOBS, M.D., BOSTON.

IN connection with the subject under discussion, perhaps this case may prove interesting. I am able to report it through the kindness of Dr. Whittier, into whose service it came at the Massachusetts General Hospital, January last, during my term as house-pupil.

The patient, living near the junction of Joy and Cambridge Streets, thirty-eight years old, mother of two children, aged eighteen and twenty respectively, was a strong, well woman till six days before entrance, without history of previous sickness or traumatism. One week before coming to Hospital, on a damp, cold day, she had worked unusually hard, most of the time out-of-doors. The next day she had a slight cough, some headache and backache, and felt tired and without appetite. She assumed she had taken cold, and thought little of it; her catamenial period was due, and to this, also, her symptoms were partly attributed.

In the next day or two, however, her headache increased in severity. She became feverish and weak, and had to take to bed. On the fourth day of her illness she was noticed to be somewhat irrational, and on the fifth and sixth days was in violent delirium, and only with great difficulty kept in bed.

She entered on the seventh day of her sickness, and the following record was made by the house-pupil: Patient a well-nourished woman of medium stature, in state of rather violent delirium, noisy and incoherent, extremely restless, struggling almost incessantly to get out of bed. Pupils alike, somewhat contracted, reacting but slightly to light. External examination of ears negative; teeth covered with sordes; tongue dry, brown; hands and feet cold and cyanosed. Nothing abnormal found on examination of lungs and heart, except slight feebleness and irregularity in action of the latter. Abdomen soft, not distended, generally resonant. No rose-spots. No apparent increase in hepatic or splenic dulness. Irritation of the skin produced the tâches cérébrales. Knee-jerk present and perhaps slightly exaggerated. No ankle clonus. No apparent hyperæsthesia, except on posterior surface of head and neck, where pressure causes facial contortions and groans indicative of pain. Further examination shows marked rigidity of posterior cervical muscles, though not sufficient to produce opisthotonos, yet sufficient to hold head in line of vertebral column, in opposition to considerable force. Catamenia present. Temperature 100.2°, pulse 81, respiration 40.

Urine by catheter: high-colored, acid, 1024, slight trace albumen, heavy sediment, excess of urates, occasional hyaline and granular casts.

In the following days she steadily failed. Though somewhat quieted by anodynes, there was almost constant movement of the arms and legs, constant incoherent delirium, which became less violent in the last day or two, and gave way to deep coma in the last six hours.

The hyperæsthesia of the cervical region continued, while the rigidity of the cervical and dorsal muscles became so marked that the position in bed was one of semi-opisthotonos; the trunk, as low as the hips, could be raised with the hand under the back of the head. The tâches cérébrales and the lividity of the extremities persisted, and large, irregularly-shaped blotches of a bluish hue appeared upon certain parts of the body. The knee-jerk was constant and somewhat exaggerated. Loss of voluntary control of the sphincters came on. Toward the end there was considerable convulsive fibrillary twitching, or perhaps better, quivering of muscles of trunk and extremities.

Temperature was never extreme. Highest on morning of death, when it was 103°.

Pulse increased in rapidity and failed in strength from the first. Last time counted was 190.

Died on the fourth day after entering the Hospital, in the tenth day of her illness.

Dr. Fitz, who made the autopsy twenty-seven hours after death, reported:

Rigor mortis present; no abnormal external appearances.

Calvaria unusually thick and dense.

Dura mater tense. Sinuses free from abnormal appearances. On removal of dura mater, the pia mater over the convexities, especially over the vertex, extensively infiltrated with opaque, yellow material, soft and friable, most abundant in furrows, but continued over convolutions. Pia mater at base showed nothing abnormal. More careful examination of brain showed small patches of sclerosis on the vertex, just below the gray matter. Behind the posterior cornu in left lateral ventricle was a cyst, the size of a cherry. Dura mater torn from base of skull: no abnormal appearances in bones of base. Roofs of middle ears crushed without disclosing abnormal appearances.

Pericardium showed no abnormal appearances, with exception of a fibrous thickening, warty in character, near the base.

Heart. Right side distended with clotted blood. Valves, cavities, and muscular substance showed nothing abnormal.

Lungs both collapsed, injected posteriorly; otherwise not remarkable.

Spleen slightly increased in size, of diminished consistency. On section, paler than normal from increase in pulp.

Kidney not remarkable in shape or consistency. On section, cortex paler than normal and more opaque.

Bladder distended with some ten ounces of urine, which was opaque and contained numerous slimy shreds; odor somewhat offensive. Mucous membrane

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, May 9, 1888.

of bladder swollen, injected, and somewhat opaque, with numerous slimy shreds and flakes.

Uterus. The interior showed injection of mucous membrane, which was besmeared with bloody fluid. A dark, corpus hæmorrhagicum in ovary as large as pea.

Stomach, intestines, and liver showed no abnormal appearances.

Diagnosis: Acute leptomeningitis, hyperplastic spleen, granular degeneration of kidneys, acute cystitis, recent menstruation, hyperostosis of cranium.

Is this a case of endemic cerebral meningitis? If so, it is an interesting one in that it is an isolated, sporadic case, and in that the pathological lesion was limited to the convexities, the basilar and spinal meninges showing no evidence of an inflammatory condition. The granular degeneration of the kidneys and the hyperplastic spleen point toward an infection. If not endemic, then it must be either tubercular meningitis or meningitis secondary to some other purulent inflammation elsewhere. The woman's general condition, her heredity, and the post-mortem appearances fail to reveal anything of a tuberculous nature; and a most thorough search, both ante- and post-mortem, did not disclose a purulent inflammatory process to which the meningitis could have been secondary either by extension or by metastasis.

TWO CASES OF SPINAL MENINGITIS.[1]

BY HENRY JACKSON, M.D., BOSTON.

CASE I. Ellen Ritchie, five years old. Patient first seen December 26, 1887. Father and mother well: two sisters, both well. Previous health good.

Two days ago, suddenly taken sick; vomited frequently; constipation; complained of headache. The mother noticed that the head was thrown backwards. Child cried a good deal, especially when moved. Head retracted; muscles at the nape of the neck are stiff; legs are flexed, and the child cries when any attempt is made to straighten them; when the thigh is flexed, the lower leg is flexed upon the thigh; pupils normal; no photophobia; no opisthotonos.

December 29th. No return of the vomiting. Perfectly conscious, and does not cry unless she is moved, especially if lifted by the shoulders. No change in neck.

January 1st. Temperature normal; pulse rapid and irregular. Appears weaker; does not complain of headache. Takes food fairly well.

January 5th. Very weak; pulse 160, irregular; temperature 105°; no chill, and no apparent cause for the sudden rise of temperature.

January 7th. Better; pulse rapid, but regular.

January 11th. Patient seen by Dr. Rotch; no change in physical condition. Dr. Rotch thought the symptoms pointed to spinal rather than cerebro-spinal meningitis.

After this time gradual improvement in all symptoms, and on January 25th was able to walk about the room without assistance. In latter part of February, child seemed to be perfectly well.

CASE II. John Philip Irvin, fifteen months. Child seen first on February 8th: father and mother both well. It was an only child, and previous health had been good.

February 4th. The mother noticed that he staggered as he walked; his head was retracted; vomited several times; constipation.

When seen, child cried if touched; head retracted; marked pallor; pupils normal; no photophobia; no opisthotonos; when thigh was flexed upon the abdomen, the lower leg was flexed upon the thigh; dyspnœa; examination of heart and lungs negative; temperature 103.5°, pulse 140, respiration 45.

February 9th. Less dyspnœa; nurses well; no change in physical condition.

February 13th. Gradual fall in temperature and pulse during last few days; sleeps fairly; no change in the head; nurses well.

February 17th. After the temperature had been normal for a few days it again rose to 103°; pulse rapid, but of fair strength and regular. In a consultation, the suggestion was made that the symptoms might be due to rheumatism in the muscles of the back of the neck. In consequence, the treatment was changed. Massage and hot applications were made to the back of the neck, instead of cold applications. Internally, salicylate of sodium was substituted for iodide of potassium and bromide of sodium.

February 22d. Has vomited occasionally; tongue coated.

February 27th. Salicylate of sodium omitted, on account of vomiting. Child seemed weaker, though temperature was normal and pulse less rapid. No change in the condition of the head.

March 4th. For several days there has been occasional vomiting; for last twenty-four hours the child has vomited every time he nursed. Temperature 98°, pulse 200; emaciation marked; pupils normal; head retracted as since the beginning.

March 6th. Sudden drop in the pulse to 120; head more retracted; subsultus tendinum; appeared to be failing fast.

March 7th. Very weak; opisthotonos for first time; when quickly moved, general clonic convulsions; conscious.

March 8th. Opisthotonos excessive; the heels and head made almost a semicircle. Pulse 200.

March 9th. Died at 6.30 A. M. No autopsy.

In both these cases the diseases to be considered were:

(1) *Tubercular meningitis*, rendered improbable by the acute onset in each case, by the absence of any evidence of intercranial pressure, and the family history. This disease is eliminated in one case by the recovery, and rendered very improbable by the whole course of the other.

(2) *Caries of cervical vertebræ* eliminated by history and absence of any local sign of inflammation.

(3) *Rheumatism of muscles of neck.* I considered this improbable, on account of the marked constitutional disturbance, high fever, rapid pulse, and by the existence of Kœnig's phenomenon; that is, flexion of the leg on the thigh when the thigh is flexed on the abdomen, which seems to indicate spinal irritation, or, at least, peripheral irritation in the sciatic nerve.

Acute cerebro-spinal meningitis. On account of the absence of any symptom of marked cerebral disturbance in these cases, I preferred the diagnosis of acute spinal meningitis, as being anatomically more correct.

PROGRESS IN DENTISTRY.

BY W. H. ROLLINS, M.D., BOSTON.

NEW FORMATION OF DENTINE.[1]

THERE are two kinds of cells which form the dentine: The odontoblasts, which are present as a peripheral layer of closely-pressed cells, with flat ends toward the forming tooth; the fibre-cells, which are pear-shaped, and lie between the odontoblasts. The fibre-cells have two processes, one extending into the pulp, the other into the forming dentine. Unlike the odontoblasts, the fibre-cells never rest with flat ends toward the dentine. The odontoblasts form the basis substance of the dentine, and the fibre-cells the dentinal fibres.

FORMATION OF DENTINE.[2]

Dentine is formed from connective tissue, first visible as a papilla, composed of medullary tissue, holding an irregular, myxomatous network. Shortly before calcification there appear at the periphery of the papilla elongated corpuscles, which are the odontoblasts. These do not change directly into the dentine, but break up into medullary tissue corpuscles, which are then directly transformed into dentine basis substance by calcification. The dentinal fibres are direct offshoots of the odontoblasts.

FORMATION OF CEMENTUM.[3]

The cement of the teeth arises from medullary tissue, which becomes the seat of a deposition of lime salts, before any cement corpuscles are visible. In the next stage of development, these medullary corpuscles are arranged irregularly around the cement corpuscles, which have now made their appearance, and remain permanently free from deposits of lime salts during the process of calcification. The cement corpuscles send soft filaments from their surfaces in radiating lines between the medullary corpuscles. The cement corpuscles and their filaments originate from the bridges traversing the interspaces in the medullary substance.

TEETH OF RABBITS.[4]

The writer denies the presence of a layer of cementum over the enamel. He also points out the marked difference in the direction of the dental tubes. In the portion of the tooth anterior to the pulp-chamber the tubes are arranged with great regularity, running in oblique courses either downward or upward, and becoming nearly horizontal as they approach the border of the dentine. In that part of the tooth posterior to the pulp-chamber the tubes are arranged very irregularly, and not at such acute angles.

RIGHT UPPER CANINE IN LEFT ORBIT.[5]

From the left orbit of a child two years old, a tumor was removed which contained a right upper canine tooth. An examination of the child's mouth showed the usual number of teeth, and the jaws were large and perfectly developed. The author of the paper considers the case unique and interesting in its bearing on the development of the jaws, and supposes that the transposition must have taken place in the early embryo, the germ developing into the perfect tooth in its new position.

THE FIRST PERMANENT MOLARS.[6]

Much has been said in support of the usual practice of extracting these teeth, but their title to longevity can only be questioned under neglect. They are the keystone molars, by means of which the integrity of the arch is maintained, and without which the jaw contracts abnormally. The extraction of these teeth at an early age is detrimental to health, for it leaves too little masticating surface, and later in life they are essential to a proper poise in the distribution of the various strains to which the teeth are subjected in mastication. Their extraction leads to a tipping out of line of the other grinding teeth, so that their surfaces do not meet fairly, and on this account mastication is imperfect.

EXTRACTION AND FILING.[7]

Extraction for the relief of crowding is not wise, as it leads to worse evils than the original one. Among these evils are a tipping out of line of the teeth, so that their masticating surfaces do not come in contact, and also spaces are formed which are difficult to keep clean, so leading to early decay. Filing, as a means of preventing decay, or to enable the teeth to be filled without wedging, cannot be too strongly condemned, for the teeth come together again after a few years, and then are more crowded than before, and more difficult to keep clean, as they are in contact over a greater extent of surface. Filing, like extraction, also leads in time to the same evils of tipping out of line, with its attendant results.

ATTACHMENT OF IMPLANTED TEETH.[8]

As a result of the microscopical examination of a tooth implanted by Younger's method, the writer concludes that the inflammation consequent to the formation of the new socket produces an infiltration of osteoblasts into the cementum of the implanted tooth, which results in bony anchylosis, thus fixing the tooth firmly in place. He believes that not only the cementum recovers its life, but also the dentine of the root, his sections showing that the dental fibres were not shrunken, and that the peripheral cells of the pulp, the odontoblasts, were alive.

He suggests that the method of implantation may be used to furnish attachments for artificial teeth in edentulous mouths, and presents a case in which this treatment was successful.

ATTACHMENT OF IMPLANTED TEETH.[9]

This writer has examined microscopically a tooth which had been implanted in the mouth of Dr. Younger, who had purposely tried to prevent anything but a soft tissue union of the tooth by working it with the tongue, and occasionally with his fingers, his object being to show that the soft tissues of the new socket united with the dried membrane of the root, and that the latter regained its normal condition. Heitzman found no living tissue between this tooth and the socket, nor were any of the tissues of the tooth alive. The only attachment was by granulation tissue, which had arisen from the new socket and entered the bay-like indentations of the root, thus forming a fairly firm attachment. He states that these bay-like indentations found in the root were produced by a process of

[9] Heitzman in Dental Cosmos, p. 334, 1888.

absorption that took place after the tooth was planted. In this respect the tooth presented the same appearances which were first pointed out in this JOURNAL in 1877, as occurring in the unsuccessful cases of transplanted teeth. This investigation of Heitzman's cannot be considered as proving that there may not be a perfect union in the case of an implanted tooth. It simply shows the condition of a tooth in which the operation has not been entirely successful. Even after the root has been partly absorbed, there may be a new formation of bone on the surface, filling up the irregular cavities produced by absorption and rounding out the root, so that it is not a source of irritation. That this takes place in transplanted teeth, I showed in this JOURNAL some years ago, and the circumstances are so similar I have no doubt that it takes place in a certain per cent. of successful cases of implanted teeth, when, after a period of doubtful utility, the implanted tooth becomes firm again.

DERMOID CYST.

One of the most remarkable of dermoid cysts is figured by Homans in this JOURNAL, page 252, 1888. It contains a great number of beautiful teeth.

MICROSCOPICAL APPEARANCES OF ENAMEL IN ERODED TEETH.[10]

The granularity of the enamel is much increased in the transverse striations of the prisms and in the brown lines of Retzius. The interspaces of the enamel are either widened or obliterated. In the latter case the whole tissue appears in confusion, looking like drops of rain on a window-pane. He regards erosion as a disease of the enamel, as the dentine, when attacked, shows only a widening of the tubes which open with funnel-shaped mouths on the eroded surface.

THE BLACK FILM OF EROSION.[11]

In all cases of erosion of the teeth there is present, as a covering to the eroded surface, a thin film of epithelial-like scales, circular in outline, black in color, and firmly attached to the surface of the tooth. Strong friction with a tooth-brush and powder daily does not remove the film, on account of its firm attachment. Hutchinson is of the opinion that this film is an essential factor in erosion, but is at present unable to explain its significance.

EFFECT OF THE SUPPRESSION OF THE SALIVARY SECRETIONS ON THE TONGUE.[12]

A case is reported in which there had been no saliva for ten years. The tongue was bright red, perfectly smooth and dry. He explains the perfect smoothness by saying that the epithelium not being kept moist by the saliva cannot assimulate the nourishment furnished it by the blood and so remains stunted. Several other cases of a similar nature are mentioned in the *Lancet*, and on page 257 Harkin reports the successful use of chlorate of potash in such cases.

MULTIPLE SALIVARY CALCULI.[13]

Three salivary calculi, weighing thirty-eight grains, were removed from Bartolin's duct in a man aged seventy. They had given rise to salivation and to pain in swallowing.

[13] Boston Medical and Surgical Journal, p. 386, 1888.

DRYNESS OF THE TONGUE IN GLYCOSURIA.[14]

This writer states that the dryness of the mouth which is such a distressing symptom in this disease is due to the strong osmotic action of the sugar in the blood.

SPASMUS NUTANS IN DENTITION.[15]

The patient a girl ten months old, when first seen, had a rotatory motion of the head; when the head was held the eyes rolled from side to side. A fortnight later, under treatment with bromide of potash, there was no improvement; but after six weeks the child was well, and had cut two teeth. There seems to be little doubt of the teeth acting as an exciting cause in this case.

TALKING WITHOUT A TONGUE.[16]

The whole of the tongue was removed for flat-celled cancer. When the wound had healed, the woman had no difficulty in speaking plainly. This case is interesting when taken in connection with others of a similar kind, as it explains in a very natural way the case of the African confessors, which is the most authentic of the various miracles of the Roman church.

About the year 466, by order of Huneric, certain Catholics, who were assembled for religious purposes, in the town of Tipasa, had their tongues torn out by the roots. They recovered however, and spoke as well as before. This is the only one of the nine miracles specified by Newman, which does not rest on merely indirect evidence.

PAIN IN THE TEMPERO MAXILLARY ARTICULATIONS CAUSED BY IRREGULARITY OF THE TEETH.[17]

The patient complained of severe pain in mastication. The teeth were sound and all erupted. None of them were tender. When the patient closed his mouth, the incisors met at the cutting edges, no other teeth touching. The molars were separated by a sixteenth of an inch. It was therefore thought probable that the pain came from the long-continued strain and pressure of the muscles and articulations as the result of attempts at mastication. A regulating plate was therefore applied with the result of bringing the under front teeth inside of the upper ones. When this result had been brought about, the molars articulated, and there was no more pain.

UNDUE PROMINENCE OF THE UPPER JAW.[18]

One of the most difficult cases for regulating is that of projecting upper front teeth, the lower incisors striking the gum far behind the upper; the usual treatment has been to extract a tooth on each side, either a first molar or a second bicuspid, and then with appliances draw back the incisors into the space thus gained. Coligan simply spread the upper arch about a centimetre in its transverse diameter, and this allowed the front teeth to fall back of their own accord. This case illustrates a tendency to which in a former report I gave the name, Progression in Teeth. It shows that the cause of the forward projection of the incisors and canines was pressure from behind. When this was removed, the pressure of the lips was enough to force back the front teeth.

TREATMENT OF ALVEOLAR ABSCESS BY INJECTING GUTTA-PERCHA.[19]

Chronic alveolar abscess is a difficult disease to treat. Almost everything has been recommended for it, and in many cases every remedy mentioned short of extraction may be tried without success. In one such case I have tried Jennings's method with success. He dissolves gutta-percha base-plate in chloroform to a thick cream, and injects the solution into the abscess cavity with a syringe.

DENTAL IRRITATION AND EPILEPSY.[20]

It is assumed that in persons subject to epilepsy, the higher nerve centres are in a state of high tension, of unstable equilibrium, so that it only takes a stimulus of definite quantity or intensity to excite the explosive discharge. To prove that the teeth, when diseased, may furnish the necessary stimulus, he gives sixteen cases in which they seem to have brought on the attacks.

ACTINOMYCOSIS.[21]

In enumerating the channels through which the fungus that produces this disease may enter the system, Eve mentions carious teeth as being of great importance. The germs may find their way not only directly through the medium of exposed or dead pulps in teeth with open cavities, but also through abrasions of the tongue produced and kept up by the sharp edges of the carious teeth. He believes the disease to be not uncommon, and thinks it has frequently been mistaken for some other form of tumor.

HEADACHE FROM WEARING ARTIFICIAL TEETH.[22]

The patient, a man in good health, had his upper teeth out and began to wear a plate. A few days after he felt a burning sensation in the roof of his mouth, which was followed by headache. On the removal of the plate the symptoms disappeared, returning whenever the plate was worn. The plate was of red vulcanite, and to be sure that the symptoms were not due to the vermillion with which it was colored a plate of black rubber was substituted, but as there was no improvement, at last a metal plate was made. This obviated the difficulty.

THE BAROMETER AND TEETH.[23]

In the majority of cases of pulp inflammation, the patients present themselves for treatment while the barometer is falling. It seems probable, therefore, that the diminished atmospheric pressure on the surface of the body leads to a distention of the superficial bloodvessels. When, as in the case of the pulps of teeth, these vessels are contained in unyielding cavities with hard walls, the distention of the vessels produces undue pressure on the nerves and so severe pain.

CHRONIC DIARRHŒA FROM WEARING A PLATE.[24]

For six years the patient had worn a red vulcanite plate. During this time he had suffered from chronic diarrhœa. On learning that the affection had begun within three months after the plate was inserted, Byrant decided this was the cause of the diarrhœa, and recommended that the patient should get on without teeth. He followed this advice and in two months was well.

ANTISEPTIC MOUTH-WASHES.[25]

An efficient mouth-wash cannot be constructed without the use of bichloride of mercury. There is no danger in using this, for in the proportion required, one part in two thousand of water, it would take one hundred days to swallow the maximum daily dose, while in point of fact there is no reason why any should be swallowed in rinsing the mouth. No doubt Miller is correct in saying that the mouth cannot be sterilized without the use of bichloride, but if we use this in a mouth-wash we must give up another eqnally important ingredient. I refer to an alkali in some form. Patients will not use any form of mouth-wash with sufficient regularity or thoroughness to keep the mouth thoroughly free from germs, and so there is always fermentation going on, and in most mouths the saliva is not sufficiently alkaline to neutralize the acids which result from fermentation, hence the need of an alkali in any form of mouth-wash which is intended to diminish decay. As bichloride and alkalies do not agree, I consider it best to use some other germicide rather than to give up the alkalies as ingredients of mouth-washes. After all, however, attention to the saliva is of prime importance, for as I have shown in this JOURNAL, if this is normally alkaline the teeth do not decay much, though in these mouths there is no reason to doubt the presence of germs with the attendent consequences of fermentation and generation of lactic acid. Where teeth are decaying rapidly the saliva is always at fault, and any treatment which does not take this into consideration will fail. It may be well to point out that a sterilized mouth is a mouth in an abnormal condition, and that the germs which are normally present in the mouth may be of some value in the economy.

KILLING TOOTH-PULPS.[26]

The ordinary way to kill a tooth-pulp is to apply a mixture of arsenic and creosote. This treatment is always attended with pain; severe and lasting some hours. Truman finds that this pain may be avoided by preparing a mixture of equal parts of arsenic and iodoform, and then after adding five per cent. of carbolic acid, applying a minute quantity to the pulp which is to be killed.

BLEACHING TEETH BY ELECTROLYSIS.[27]

The tooth to be bleached is to be flooded with acidulated water. An electrode is to be placed in the cavity and connected with the negative pole of a battery. Connect a platinum needle with the other pole and rub the needle over the surface of the tooth.

COMBINED FILLINGS.[28]

The advantages of combining amalgam and gold in the same cavity are the therapeutic effects which result, teeth which were soft becoming harder in a few months. This is due to the diminution in the intensity of thermal shocks, and to the electric relations which are the result of this combination of metals. These electric currents act as germicides, thus keeping a sterilized zone about the fillings. In the case of combining tin and gold in the same cavity, the oxida-

tion which results is supposed by this writer and others to render the dentine less liable to the attacks of germs.

Various improvements and methods have been worked out during the year in connection with the operating-room and the laboratory. Among these may be mentioned a new way of casting aluminum for the plates for artificial teeth. This metal shrinks so much that it has not been available and is so light that it is difficult to make it fill the mold in casting. To overcome these difficulties it is now alloyed with a small per cent. of gold and forced into the mold by means of air pressure.

Melotte has introduced a compound of clay and glycerine which is used to take an impression of a broken-down root or for similar purposes. Then a rubber ring is fastened around this and a special fusible metal cast onto the impression. It thus becomes possible in five minutes, without leaving the operating room, to get a metal cast of the root, and by again casting on this die, to obtain a counter-die, which can be used to strike up a plate or any part of a gold crown. With the new compound blowpipe of Knapp's which occupies little room in the instrument case, it is a simple matter to make and fit a gold crown in an hour. These inventions of Melotte are of great value in filling teeth in which the walls are so thin that a metal filling is sure to be short-lived. By filling the cavity with gutta-percha and then striking up a piece of gold to cover it, we get a filling that can be inserted in a few minutes and which under the circumstances is the most durable known.

Copper amalgam made by electricity, as described in this JOURNAL, is now in extensive use in soft teeth, where its color is not objectionable. Miller has repeated his statement of last year, and claims that there is no filling so durable as one made by folding layers of gold and tin together and then wedging them into the cavity, which must *not* be dry, if the best results are to be obtained.

It is now claimed that the method of vulcanizing rubber plates for artificial teeth under steam heat at a temperature of 320°, in a copper vulcanizer, is entirely unnecessary, that as good a result can be obtained by placing the plate in a common sauce-pan, covering it with glycerine and heating to the requisite temperature. Vulcanizers have been in use ever since the introduction of rubber in dentistry. They are expensive and dangerous, a number of lives having been lost by their explosion, it is therefore fortunate that they are to be things of the past, and Dr. Anjubault deserves the thanks of the profession for not following the ordinary fashion in dentistry of patenting his invention.

Clinical Memorandum.

A CASE OF CEREBRO-SPINAL MENINGITIS OF THE PNEUMONIC TYPE, WITH PAINFUL JOINTS AND WORMS.

BY A. L. MASON, M.D., BOSTON.

THE following case is reported on account of the complications which attended it; namely, lobar pneumonia, painful joints, and worms. It is hard to see how the presence of worms can be anything more than an accidental coincidence. Dr. S. G. Webber, however, in his valuable history of the epidemics of cerebro-spinal meningitis, says that lumbricoids were found in many instances during certain epidemics in France and Italy, and were thought to be a characteristic symptom of the disease; also that the pneumonic type was especially prevalent in this country among the soldiers at the time of the War of 1812.

The patient, a delicate-looking school-boy, five years old, came to the City Hospital, October 23, 1888. Three days before, he had been attacked by abdominal pain, vomiting, chills, headache and nose-bleed, thirst, marked dyspnœa, and mild delirium.

On admission, his tongue was dry, the head was drawn far back, the cervical spines were tender, the left wrist was very painful, not swollen. Over the left lower lobe were dulness, broncho-vesicular breathing, and moist râles. There was an eruption of herpes about the mouth. The bowels were costive. Temperature 106° F., pulse 120, respiration 60.

During the next ten days the disease was at its height. Signs of pulmonary consolidation became more marked, with bronchial breathing, increased voice-sounds, and abundance of moist râles. There was retention of urine, and the cerebro-spinal symptoms, vomiting, retraction of the head, and great pain in the spine, continued.

There were no petechiæ, and the mind was generally clear. The wrist was a source of great pain, and was kept in a splint. Priapism was observed.

Toward the end of the second week of the disease, the temperature rose daily to 104°, and the pulse ranged from 115 to 125; but on the sixteenth day the thermometer showed no fever, and the pulse was 100. On this day the patient passed a lumbricoid worm seven inches long, but two or three anthelmintic doses failed to bring away others. The painful symptoms did not abate entirely, although from the sixteenth to the twenty-fifth day the temperature was normal, the pulse 100, and the respiration 25. The head ached and remained still thrown far back, with tender cervix. The chest-dulness, bronchial breathing, and moist râles continued. Constipation was marked, and there was vomiting. The patient was now considerably emaciated, but the condition of the lung continued slowly to improve.

On the twenty-sixth day, however, there was a relapse of the cerebro-spinal symptoms, which lasted until the fortieth day. More severe pain was noted, accompanied by screaming. A fresh eruption of herpes about the mouth occurred. The temperature ranged between 96.5° and 103°, the pulse between 110 and 130.

At the end of six weeks it was noted that the child began to take considerable milk and had a bright expression. Retraction of the head was less marked, and he slept well.

A week later, although greatly emaciated, he was calling for food, had no more pain, and the head was freely movable. After nine weeks he was up, gaining in flesh, strength, and color. The legs were weak, and there was slight want of control. A little dulness remained in the left back.

January 3d. The record says: He plays about the ward all day. Rapid gain in flesh, strength, and color. Bowels move daily. Appetite good, sleeps well, no cough.

A week later he was discharged, well, after eleven weeks in the Hospital. The only drug which ap-

peared to be of service was morphine, which was frequently given in doses of ten to twenty minims of the officinal solution. Brandy, also, was freely administered.

Two months later the child was brought back to the Hospital with a recurrence of the cerebro spinal inflammation, which resulted fatally in three days. Headache, marked retraction, and opisthotonos were observed. These symptoms were said to have followed a fall upon the head. No autopsy was permitted.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

REGULAR meeting, Wednesday, May 9, 1888.

DR. T. M. ROTCH exhibited the wood-cut of a slate pencil which was brought to him by Dr. Morrison, of Providence. The case came under the latter's care and was briefly as follows: a boy seven and one-half years old, fell, as he was going to school, on a new slate pencil which had been sharpened. The pencil entered the thorax in the fourth left intercostal space, and went into the chest to the point where it was broken off, a length of about four and one-half inches. From the position, and the length of the pencil, it was considered that it must have entered the heart. The child presented symptoms such as one would get in perforation of the heart, according to the recorded cases. The pencil was extracted, and the boy at once fell into a state of collapse with cessation of pulse and respiration, and it was thought that he was dead; but after somewhat protracted efforts at artificial respiration, reaction ensued, and the child after passing through an acute attack of pericarditis with effusion, recovered.

DR. C. W. TOWNSEND read a paper on

ENDEMIC CEREBRO-SPINAL MENINGITIS.[1]

DR. HENRY JACKSON reported

TWO CASES OF SPINAL MENINGITIS.[2]

DR. HENRY B. JACOBS reported

A CASE OF CEREBRAL MENINGITIS.[3]

DR. T. M. ROTCH said: I think the ground has been very thoroughly gone over by Dr. Townsend in his paper. The cases were of a great deal of interest to me; I had an opportunity of seeing them with Dr. Townsend and Dr. Jackson. The temperature in cerebro-spinal meningitis, I think in many cases of children at some time of the day or on certain days will be found to be markedly high and the pulse quick. In that way we will have valuable aids in making the diagnosis between tubercular and cerebro-spinal meningitis. The other points of diagnosis, as to to the slow onset and the hereditary taint, are, I think very fallacious. We have to take into consideration at the same time the age of the patient; especially when the spinal or the tubercular meningitis occurs in the infant. The younger the infant, the more does the tubercular meningitis approach the form of ordinary meningitis, and in the beginning it is almost impossible to differentiate them. That is, the type differs somewhat, according to the age, and very often we do not have a slow onset in the young child. The temperature as a rule, is not so high in the tubercular as in the cerebro-spinal form. The latter disease probably represents at times as high a temperature as almost any disease where recovery takes place.

I am sorry that I was not able to bring the chart of a case where the temperature ranged from 107 to 108 for a long period of time, with the final recovery of the child, but with lesions, apparently, of the brain, which kept the child from developing as rapidly as other children do; but finally, I believe, he came out a bright boy. There were some motor disturbances, remains of which are still to be found in this case. The second case of Dr. Townsend, which I think I also saw with him — the one that extended over a period of months — is interesting to me in relation to Henoch's idea that there is a separate spinal meningitis, differing from the epidemic infectious meningitis, and that the cases all recover. I followed, with Dr. Townsend, this case with a good deal of interest, but it finally died, although it seemed to follow out the typical symptoms described by Henoch. And I very much doubt whether there is really a different disease. I think rather it is a separate phase of the general disease.

In speaking to Dr. Jacobi a few weeks ago, when he was here, he said that he had seen these cases where there was an epidemic, and he also doubts whether there is any separate disease.

Dr. Jackson's second case was also interesting. I very kindly did not speak of my having seen it. I have seen cases where I have often made mistakes in children, in the first two years, where it seemed as if they did have meningitis, and yet where they were favorably affected by salicylate of sodium and turned out to be rheumatism; that is, the extremely hyperæsthetic condition which is very likely to be present in cerebro-spinal meningitis is exceedingly difficult to differentiate from the hyperæsthetic condition of muscular rheumatism, in young babies. When young babies have rheumatism, it affects them much more violently than the older child. Even a slight rise of temperature will cause nervous symptoms which very closely simulate the symptoms of meningitis. There is at times retraction of the head and of the legs, and in this case of Dr. Jackson's, it was not at all certain that we had Kernig's symptom. As the case turned out, I think it was probably cerebral meningitis. I think it is right, however, to recognize that it is at times difficult to differentiate these cases.

DR. FOLSOM: I have little to say, Mr. Chairman. I had one of the largest dispensary districts at the time of the epidemic of cerebro-spinal meningitis, sixteen years ago, and I saw quite a number of cases. There are two or three points regarding diagnosis, to which no allusion has been made this evening, which seem to me to be very interesting if we are to be on the lookout for these cases now, for it may be coming around again. In the early stage of the disease the persistent retraction of the head, the opisthotones, is not always to be found. In fact, it is sometimes quite a late symptom. If I remember correctly, whenever autopsies were made the lesions were found at the base of the brain, and in the cervical region,

[1] See page 52 of the Journal.
[2] See page 58 of the Journal.
[3] See page 57 of the Journal.

and in the lower dorsal and lumbar region, a great portion of the dorsal region sometimes being quite free, and never being involved to the same extent as the other portions. In all the cases which I saw there was very great pain on motion in the lower dorsal and lumbar region. In the earlier stage of the disease, and in a great many cases throughout the disease, where there was no opisthotonos, and where there was no marked retraction of the head, I found that in attempting to move the head from one side to the other, without moving the shoulders with the head, very great pain was caused. In the same way, in trying to twist the trunk on the pelvis, great pain was caused.

My experience about the temperature has not been the same as Dr. Rotch's. From 102° to 103° has been the most common highest temperature. If I remember correctly, none of my cases went beyond 104.° At all events, the temperature was very much lower than the temperature in typhoid fever. It is possible all do not know that during the war this disease was very troublesome, and was very often diagnosed as typhoid fever, and one of the points in diagnosis was that the temperature was not so high as in typhoid. There is another symptom which I remember occurred very frequently in the early stage of many of my cases, and that was very severe violent pain in the epigastrium. I do not remember whether it is mentioned in the text-books as one of the symptoms or not, but it is mentioned in some of the monographs on the subject. The pain may come on very suddenly, and with the very greatest degree of violence, the individual having appeared so well within a short time that it is very difficult to account for it. I remember one case of a gentleman whom I saw, who, before I saw him, had been supposed to have been poisoned by corrosive sublimate. He was at a barber's, and had been shaved, and the barber so far as he saw noticed absolutely nothing about the gentleman. He went immediately to the water-closet, from the barber's, and failed to appear a half an hour afterward, when a gentleman came to the hotel to keep an appointment that he had made with him. It was found that he was last seen going to the water-closet. The door was locked, and there was a confused sound within. The gentleman was found partially conscious with a severe pain in the stomach. It had been supposed to be poisoning of some kind, and he had been treated with white of egg, etc. It was a typical case, throughout, and the gentleman finally got well.

It seems to me that it is a matter of very great difficulty to differentiate the disease from tubercular meningitis in some cases, and it seems to me that the most constant point of variation is the fact whether or not the lower dorsal and lumbar region is involved. As I say, of my cases that was a constant symptom. Whether it is always otherwise in tubercular meningitis or not I do not know, but in the only case where I have had any very great doubt, there was no pain in the lumbar region until after a week of the disease; but there was tenderness and it amounts probably, I think, to a diagnosis of cerebro-spinal meningitis. So it seems to me, but still the case is in doubt. As I say, in my experience there has not been that marked difference in the temperature which Dr. Rotch has observed. So far as I have seen, the temperature may go on very nearly alike, with no more than a degree or so of difference.

DR. ROTCH: It was in reference to children that I was speaking. The temperature does not run so high in adults, but in young children it is often, as I said before, remarkably high at certain times and by its variation is valuable for differential diagnosis, from typhoid which presents a more uniformly moderate temperature, and is a mild type of the adult typhoid.

DR. VICKERY: There is one question that I would like to ask: In Henoch's intermittent form, do the cases all recover?

DR. TOWNSEND: In the cases that occurred in Berlin they all recovered. In some of the cases reported by Smith and one or two others, recovery did not take place.

DR. VICKERY: Take such a case as your own; would it not be very hard to exclude tubercular meningitis?

DR. TOWNSEND: I think that, with such a long continuance of the disease, three months, there would have been signs of tuberculosis elsewhere.

DR. VICKERY: That is the point on which the diagnosis rests.

DR. TOWNSEND: That, with the exact correspondence with the cases reported by Henoch and others, in the characteristic symptoms; and also the presence, in my case, of an eruption, which you would not find in the cases of tubercular meningitis.

DR. PUTNAM: I would like to say a single word. Dr. Mills, of Philadelphia, who is an accurate observer, has recently called attention to observations that he has made in one or more cases of cerebro-spinal meningitis, that the symptoms showed apparently the presence of multiple neuritis, as it has been described of late, apparently complicated with them; that is, a portion of the symptoms were identical with multiple neuritis, and that seems to me of interest, in view of the fact which has been alluded to, that the signs which have been considered characteristic, the contraction of the head and opisthotonos, sometimes scarcely occur at all, and often not until quite late, so that a mistake in diagnosis from this cause might arise; and it is also, I think, interesting from the fact that, even in the Northern climates, multiple neuritis is occasionally an infectious disease.

DR. JACKSON: I would like to ask Dr. Folsom if you often find in cerebro-spinal meningitis the symptoms of intra-cranial pressure which are quite common in tubercular meningitis, the strabismus and the change in the rhythm of respiration, due to pressure?

DR. FOLSOM: There was not strabismus except in late cases, but there was a change in the rhythm in the severer cases. With regard to the temperature, the majority of my cases were children.

DR. MASON: I had occasion to look up this subject a little, four or five years ago, after seeing a few cases, and reported five cases in the *Medical Journal*; and in these cases, which were all in adults, the temperature did not rise to any great height; 103°, I think, was the highest. One or two of them were very little above the normal. The pulse, also, was low, from 60 to 100, rising in no case above 100, except near death in one or two cases which were fatal. It became very rapid, of course, before death. Probably, in infants, the symptoms are more acute. When effusion has taken place, after a few days, I presume that the marked physical depression which follows is due to pressure on the brain and spinal cord, and in one instance which I recall, in a man, the temperature fell

to 96.2°, and remained below normal for some time, the pulse rising gradually until death; and in one case, also, I noticed symptoms which led to the supposition, as Dr. Folsom remarks, that there might have been mineral-poisoning, so that a stomach-pump was thought desirable. It was not used, however.

In the case reported, where there was no inflammation of the cervical meninges, I think it would be difficult to make a positive diagnosis of cerebro-spinal meningitis. Last fall we had a case at the City Hospital, one of the four or five which have occurred there in the last four years of this disease, in which the affection assumed the pulmonic form; that is, there was an acute lobar pneumonia of the left lower lobe, with retracted head and all the characteristic symptoms of cerebro-spinal meningitis. There was herpes on the lips, and, in fact, the child presented the typical appearance of cerebro-spinal meningitis, and got well after ten weeks. He went out of the Hospital apparently perfectly well, and in a few weeks more came back with a relapse, and died with opisthotonos and all the characteristic symptoms renewed. Unfortunately, there was no autopsy. These few cases are the only ones that I have seen for several years; and out of some thirty or forty cases of cerebral meningitis at the Hospital, I think there were but four or five of this disease. I have nothing more to say, except in relation to the epigastric pain. In my second case I spoke of that pain; but the child had been treated for abdominal disease before I saw it, and applications had been made to the abdomen.

(To be continued.)

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

W. H. TAYLOR, M.D. SECRETARY.

The eleventh annual meeting was called to order at 12.15 P. M., by President Winsor, at the rooms of Boston Medical Library Association, June 12, 1888. Present, sixteen members.

The Treasurer made his report, showing a balance of $26.85 in the treasury at date. The report was accepted, and an assessment of three dollars for the current year was declared.

The President appointed a committee of three to nominate a list of officers for the ensuing year. The committee reported the following list which was unanimously adopted:

President, Med. Exr. J. G. Pinkham, Lynn; *Vice-President*, Med. Exr. A. F. Holt, Cambridge; *Corresponding Secretary*, Med. Exr. B. H. Hartwell, Ayer; *Treasurer*, Med. Exr. C. C. Tower, South Weymouth, *Recording Secretary*, Med. Exr. W. H. Taylor, New Bedford.

President Pinkham thanked the Society for the honor conferred on him, and made a few remarks concerning the best ways of forwarding the Society's interests. The President appointed the following gentlemen Standing Committee for the ensuing year: Med. Exrs. Draper, Presbrey, and Winsor.

Voted, On motion of Med. Exr. Draper, to empower the Standing Committee to bind the Transactions of the Society in a suitable manner.

Med. Exr. Holt deplored the inactivity of members in the matter of presenting papers, and hoped that members will feel it their duty to the Society to make efforts to increase the interest of the meetings.

Voted, On motion of Med. Exr. Winsor, that the subject for discussion at the October meeting be Poisoning by Arsenic, and that members be notified of this vote as early as convenient.

Med. Exr. Winsor made some remarks regarding his term of office as President, and read an interesting account of

A DISPUTED CASE OF ACCIDENTAL DROWNING.

The death was probably due to an epileptic attack while bathing. Certain questions of violence arose in the minds of the public, and an autopsy was held by private parties, without definite result as to determination of cause of death. A prominent question in Dr. Winsor's mind was, whether he should have made an autopsy to satisfy public sentiment, believing as he did, that the case was purely one of accidental drowning.

In the discussion which ensued, Med. Exr. Morse reported a case of an epileptic who met his death by drowning while in an attack.

Med. Exr. Holmes reported a case of drowning in a tub, the subject being a child of twenty-one months, and the water but one and three-quarters inches deep.

Med. Exr. Presbrey reported a case of drowning in a little rill of water from melting snow, the locality being dry when the body was discovered.

Med. Exr. Taylor reported a case of drowning in a little water contained in the imprint of a horse's hoof in mud, which subsequently became frozen.

Med. Exr. Wright reported a case of a man who vomited the contents of his stomach, and, lying face downward, was literally drowned in the fluid.

Med. Exr. Holt believed that the office of medical examiner was created in the interest of the public and not that of the official, and would make autopsy in any case where public sentiment demanded it.

Med. Exr. Paine reported a case of drowning showing necessity of an autopsy.

The subject was further discussed by members Holmes and Morse.

Recent Literature.

Intubation of the Larynx. By F. E. Waxham, Professor of Otology, Rhinology and Laryngology, College of Physicians and Surgeons, Chicago. Pages 110. Published by Charles Truax, 75 and 77 Wabash Ave., Chicago, 1888. Price $1.25.

This small volume, upon a most important subject, should be read by all who are likely to be called upon to treat laryngeal stenosis in children. It should be read especially by those surgeons who are still sceptical regarding the merits of intubation. The whole subject, as it is understood to-day, is in this volume, presented clearly, concisely and with authority, by Dr. Waxham. In speaking of the comparative merits of intubation and tracheotomy the author says that "by reference to the comparative statistics of these operations, it will be seen that intubation is not secondary in importance to tracheotomy, for not only are we permitted to operate where tracheotomy would not be allowed, but after operating we can then save as large a percentage of cases at all ages, and a much larger proportion under the age of three years." There can be no stronger argument in favor of intubation than this. The book is well printed and illustrated.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 19, 1888.

THE MASSACHUSETTS HEALTH REPORT.

THE nineteenth annual report of the State Board of Health of Massachusetts falls nothing short of the highest standard of the Board's work during the many years of its usefulness. It is so compact with information on matters pertaining to the public health, that no abstract or review can do justice to it.

Of recent legislation the most important is the Act of 1886, to protect the purity of inland waters, by which the general oversight and care of such waters was committed to the State Board of Health. Under this act the Board was authorized to employ such experts as were necessary for carrying out its provisions, to recommend legislation and suitable plans for main sewers, to report its proceedings under the act, and to submit estimates of expenses. It was also required to make examinations of such waters with reference to their domestic use, and authority was granted to conduct experiments for determining the best practicable methods of sewage purification and disposal. The Board was also required to consult with and advise the authorities of cities and towns, and also corporations, firms and individuals, with reference to existing or proposed systems of water-supply and sewerage. To these ends the Board has organized: (1) A series of chemical analyses of all the domestic water-supplies of the State; (2) Examinations with reference to the presence of the various forms of vegetable life; (3) Bacteriological investigations; and (4) Experiments to ascertain the comparative value of various soils for sewage irrigation. The work already done, both scientific and practical, under this law, occupies over a hundred pages of the report and prepares the way to a solution of some of our most difficult sanitary problems.

During the year there were examined 4,870 samples of food, of which 35.05 per cent. were found to be adulterated or not conforming to the statutes, including 3,080 samples of milk, of which 38.33 per cent. was below the standard or adulterated. Of 550 samples of drugs, 400 were of good quality. In the five years, 1883 to 1888, of the operation of the act, the percentage of adulteration found has been reduced very materially, and in milk from 83.9 to 38.33.

An extended report on oleo-margarine shows that it is probably not quite so digestible as butter, very nearly as nutritious and not so readily becoming rancid; that it is wholesome if properly made of good material, but that if sold as butter there is a commercial fraud, by virtue of which the purchaser pays for what he does not get—a not uncommon deception. No evidence was found of adulteration or of use of uncleanly or unwholesome material, coloring matters only causing deception as to quality.

Weekly mortality reports are sent to the Board from the larger cities and towns representing a population of 1,100,000, or a little more than one-half the population of the State. They have been of exceeding value as stimulating local authority to accurate registration. In his summary of them, Dr. Abbott has been enabled to present some comparisons of mortality by weeks, not possible in his *résumé*, in the health report, of the salient points of the registration report of vital statistics.

Dr. Pinkham's excellent article on the ventilation of school-rooms heated by stoves, shows such excellent results, that we suspect much of its success to be due to the supervision of so expert a sanitarian. But it might do much less well and be well worthy of imitation.

An unusual immunity from infectious and contagious diseases is reported for the year, and although the Board made several investigations with reference to special outbreaks, the results went chiefly to show carelessness in disposal of filth or in allowing too free communication between the well and the sick, and to repeat the often-learned lesson of the need of vaccination.

A further investigation which is being made into the subject of trichinosis in swine, and tuberculosis in cows, is referred to in connection with a proposed investigation by the Massachusetts Society for the Promotion of Agriculture.

HYPERTENSION OF THE ARTERIES: THERAPEUTIC INDICATIONS. I.

AN admirable study of the subject of arterial hypertension, by Henri Huchard, of Bichât Hospital, has recently appeared. It is now a well-recognized fact that in diseases of the cardiac and blood vascular system there exists an important distinction between the *valvular* cardiopathies and the *vascular* or *arterial* cardiopathies: — the first beginning at the orifices of the heart and being characterized by a tendency to lowering of the arterial tension; the second having the arteries for their origin, and being characterized by a tendency to hypertension of those vessels.

Huchard establishes two divisions of hypertension: (1) temporary, (2) permanent. To the first head,

cases like this belong: A woman, aged sixty years, affected with *arterial* cardiopathy (arterio-sclerosis of the heart), of arythmical form and without any souffle, entered the hospital for violent attacks of pseudo-cardiac asthma. Crises of dyspnœa came on paroxysmally every evening, lasting nearly all night, there were no signs of pulmonary œdema or congestion. Sphygmo-manometric observations showed a considerable augmentation of the arterial tension; and auscultation discloses a *marked diastolic resonance* of the aorta, a sign to which Huchard attaches much importance. The precordial shock was energetic; the heart beats were strong, though arythmic; the pulse was close, concentrated (that is, not easily felt under the finger), almost vibrating, and a little irregular. The urine was normal. This patient had been dosed with digitalis, to the great aggravation of her symptoms. Under a treatment calculated to reduce vascular pressure (blood-letting and an exclusive milk diet) she became better, and left the hospital in a fair state of recovery.

Huchard contrasts this case with another which came before the hospital clinic, about the same time, and which was diagnosticated as *valvular* cardiopathy, and in which there was marked mitral constriction and insufficiency. The pulse was "feeble, compressible, unequal, irregular, intermittent and rapid;" the lungs were congested at both bases; the right cavities of the heart were dilated; and there was a dyspnœa which was constant, though paroxysmally worse at times. Here the sphygmo-manometer revealed depressed arterial tension. The indication was clear — the cardio-vascular tonus was to be raised, and digitalis proved as beneficial in this case as it was detrimental in the foregoing.

"Everybody knows" adds Huchard, "that not all palpitations are tributary to digitalis;" and the same may be said of cardiac dyspnœa, which is sometimes relieved by nitro-glycerine when the so-called heart-tonics fail. The same general truth applied to some cases of metrorrhagia or hæmoptysis where there is high arterial tension, and where ergot and digitalis, by aggravating this tension, favor the hæmorrhage rather than check it. There we witness the triumph of sedatives and calmatives (such as opium and ipecac), of tri-nitrine, of nitrite of amyl, of aconite, of the iodides, all of which lessen arterial tension. We get, moreover, a hint in explanation of the want of success which sometimes attends the treatment of epistaxis in young people and in arthritic persons by perchloride of iron and ergot. We see also why the palpitation of the anæmic and chlorotic are aggravated by digitalis and the usual tonic treatment of these cases. Here there is the element of vascular spasm to combat, and the immediate consequence of vascular spasm, hyper-arterial tension.

Huchard has some good remarks, in connection with the subject of chloro-anæmia, respecting the exaggerated excitability of the vaso-moter system in these patients, as evinced by the coldness of the extremities, the localized attacks of algidity and ischæmia, the frequent alternations of pallor and redness of the face, the emission of clear, limpid, and abundant urine, etc. The functional murmurs at the mitral and tricuspid orifices are of great interest, and are due (according to Huchard's explanation) to arterio-capillary spasms and consequent temporary dilatation of the heart's cavities and orifices.

Into the subject of true angina pectoris (in which arterial tension is permanently exaggerated) and the pathogeny of this disease, as well as other conditions characterized by permanent hypertension, we have not space to enter in this number.

ON THE VALUE OF SALOL IN THE TREATMENT OF ACUTE RHEUMATISM.

Dr. J. Rose Bradford, of University College Hospital, publishes the results of sixteen cases of rheumatic fever treated with salol.

The cases were all of average severity; temperature from 101° to 103°. In two of the cases, pericarditis and endocarditis resulted; in one of them there was an attack of hyperpyrexia (temperature reaching 110°) before the pericarditis. The salol was given in the most severe cases in doses of ten grains every hour till the temperature came down; in cases of moderate severity, the dose was ten grains every two, three or four hours. It was sometimes given in milk, sometimes in plain water, sometimes in soda-water.

Dr. Bradford's conclusions are as follows: (1) As an antipyretic, salol is decidedly efficacious in rheumatic fever, its use being followed by a rapid fall of temperature within twenty-four hours from the commencement of its administration. To produce this rapid fall, as much as ten grains every hour should be given. It does not, however, prove to be quite as reliable, as an antipyretic, as salicylate of soda. (2) It is inferior to salicylate of soda in relieving the joint pains. (3) Cases of relapse are just as likely to occur after salol, as after salicylate of soda. (4) Salol is superior to salicylate of soda in not producing, to as great an extent, the deafness, noises in the head, etc., so common with the latter drug. Salol is better tolerated by the stomach than salicylate of soda, nor is it so likely as the latter to produce unpleasant toxic symptoms. Its administration is sometimes attended with carboluria: this is explained by its chemical composition, salol being a compound of salicylic acid and phenyl.

Dr. Bradford adds, in conclusion, that the results obtained with salol are simply those that would be expected on the supposition that it owes its activity solely to the salicylic acid it contains. The fact that deafness, noises in the head, etc., are not so common after its use, is simply because less salicylic acid is given. Its one advantage appears to be that its taste is more pleasant; but this is of comparatively small moment, as the taste of sodium salicylate can be effec-

tively covered. The latter, moreover, has been successful in cases where salol has failed, and has proved more effective in relieving the joint pains.

MEDICAL NOTES.

— The alarming complications which may attend even the mitigated form of the duello which prevails in France, is illustrated by the following paragraph which was thought worthy of being telegraphed under the Atlantic to a morning paper:

"There seems no reasonable doubt of Boulanger's recovery within a fortnight or so, although his wound appears to threaten him with all sorts of unpleasant complications, such as lockjaw or the less familiar complaint of embolic, caused by clots of blood in the bronchial tubes, or, what is still rarer, suffocation by hæmaturia in the respiratory channels."

— At the Commencement Exercises of Union College, June, 1888, the honorary degree of LL.D., was conferred upon Mr. Lawson Tait, F.R.C.S., Professor of Gynecology, Queen's College, Birmingham, England.

— Cases have lately been reported in the *Journal of the American Medical Association* of acute rheumatism in infants of eleven days and two months of age, respectively.

— We learn from the *Lancet* of the use of a new material for absorbing and deodorizing fæcal matter and urine, namely, common slag, for the efficiency of which strong claims are made. Its cost is small (five to ten shillings per ton, including crushing and carriage), and it is said the quantity necessary for accomplishing the defecation of sewage is a third less than of ordinary dry-earth. Its method of use is like that in the common earth-closets, and a sample which had been in use for five weeks, gave no smell whatever.

— Dr. Austin Flint, of New York, has recently written on the natural history of the medical student. He classifies the specimen thus: (1) Good students, forming 25 per cent. of the graduates, and marked 80 per cent. or upwards on their examination; (2) The *average*, being 45 per cent. of the graduates, and attaining marks of 70 to 80 per cent.; (3) The poor, forming the other 30 per cent., some of them approximating very closely in scholarship to the plucked. Such, he says, seldom do any credit to themselves or their profession.

— It will be remembered that the late Mr. Roscoe Conkling developed his fatal mastoid disease soon after protracted exposure in the "blizzard" of March last. Dr. Frank Allport, of Minneapolis, Minn., writing in the *Northwestern Lancet*, says that during a practice of five and one-half years in that city, and with a total number of seven hundred and sixty-two ear cases, he has opened the mastoid twenty-five times, always finding pus. Comparing this proportion with that observed in other cities, Dr. Allport concludes that the climate of Minneapolis, with its enormous extremes of temperature from winter to summer, has a special tendency to produce mastoid disease as it has towards catarrhal affections generally.

— A London correspondent of the *Journal of the American Medical Association* quotes Sir Andrew Clark as having made the remark: "I worked twelve years for bread, twelve years for butter, and twelve more for the luxuries of life." Sir Andrew, the other day, received a fee of £5,000 for going to Italy. Sir Andrew Clark's first acquaintance with Mr. Gladstone arose in connection with his visits as Mr. Clark to Mr. Gladstone's Convalescent Home, since when they have been great personal friends. He is stated to have been one of the first to adopt the plan now general in London, of writing out elaborate dietaries for his patients.

— *The London Medical Recorder* gives the substance of a parliamentary paper, issued by the Home Office, containing a report showing the number of experiments performed on living animals during the year 1887, under license, distinguishing painless from painful experiments. The total number of persons licensed to perform such operations in England and Scotland was 82, all (save one foreign graduate) graduates of a British university or fellows or members of royal colleges. Of these 64 exercised their right. The buildings where such experiments are allowed to be made are twenty-six in number — nine in London, nine in the provinces, eight in Scotland. The number of experiments was 1,220, of which 582 were performed without anæsthetics. These were, with very few exceptions, simple inoculation experiments, and were consequently painless. The experiments were — physiological, 237; pathological, 703; or therapeutical, 380. The number of cases in which pain has been unavoidably inflicted during experiments conducted under certificates dispensing with anæsthetics, or with the killing of the animal on recovery, was 71 — 2 being physiological, 21 pathological, and 48 therapeutical. Comparatively few vivisections, properly so called — that is, involving a distinct surgical operation on a living animal — were practised during the year. In all cases in which such experiments have been performed under the certificate dispensing with the slaughter of the animal before recovering consciousness, it has been made a condition that the wound should be rendered painless by antiseptic treatment, and, that failing, that the animal should be destroyed. This condition has, the inspector believes, been faithfully fulfilled. The animals on which pain was inflicted were two cows, 12 calves, 1 cat, 32 rabbits, and 24 frogs. In Ireland there are only four persons licensed and the experiments (11 in number) were all painless.

NEW YORK.

— The first trip of the St. John's Guild Floating Hospital this season was made July 9th, and it is announced that four trips will be made each week, instead of three, as heretofore. Since last year $7,000 has been expended by the Guild on improvements, a large bath-room, with seven tubs having been fitted up

on the hospital boat, and a new wing having been added to the Seaside Hospital.

— A dispensary for the treatment of diseases of the nose, throat and lungs, has been organized in Brooklyn. The medical staff is to consist of Dr. Sidney A. Fox, physician in charge; Dr. Thomas R. French, physician for diseases of the throat and nose; Dr. Benjamin F. Westbrook, physician for diseases of the lungs; and Dr. George R. Fowler, consulting surgeon.

— Dr. T. Matlach Cheesman, a prominent New York physician, died at his country-seat at Ridgefield, Conn., on the 7th of July, in the sixty-fourth year of his age. He was for many years connected with the 7th Regiment, and during the late war he served with distinction in the medical corps of the army.

Miscellany.

METHODS OF DISINFECTION AS TESTED AT THE QUARANTINE STATION BELOW NEW ORLEANS.

No scientific report published by the government this year has been more important than that just made by Dr. J. J. Kinyown, assistant surgeon at the Marine Hospital Service, upon the germicidal powers of the different methods of disinfection practised under the direction of the Louisiana Board of Health at the quarantine station below New Orleans, of which we find a summary in *Science* for July 13th. The report is important, not only because it shows the degree of protection against the importation of infectious diseases through the important port of New Orleans; but also, since the methods of disinfection practised at other quarantine stations are similar to those in use there, the experiments show approximately the efficacy of each mode of disinfection, and suggest changes that should be made in their use. The three methods of disinfection tested were by the use of bichloride-of-mercury solution, the application of dry and moist heat, and fumigation with sulphur dioxide. Dr. Kinyown finds the first of these methods defective, because of the difficulty of getting the disinfecting-agent into cracks and corners, carpets, rubber goods, the under sides of decks, and into lockers, etc. He discovered in all these localities and articles that the micro-organisms existing before the disinfection had not been destroyed, and he found them as plentiful on the floor of the forecastle of one ship, that was exceptionally filthy, after it had been drenched with bichloride of mercury for an hour, as before. Dr. Kinyown recommends, that, in order to make this mode of disinfection more effectual, the bichloride of mercury be applied with a spray produced by a connection with a steam-boiler, and that it be applied after fumigation by sulphur. The results from the application of dry and moist heat were the most satisfactory of all. Cultivations of various disease-germs exposed to a dry heat of 80° C., and afterwards to steam at a temperature of 100° C., were, with few exceptions, destroyed. Dr. Kinyown thinks, that, in order to secure absolute protection, the heat should be made greater and the time of exposure increased. In eleven experiments seventy-four disease-germs were placed in vessels among articles to be disinfected by the use of sulphur dioxide, but only sixteen of the whole were destroyed, or less than twenty-two per cent. Dr. Kinyown has very little to say about this method of alleged disinfection, except to recommend that the sulphurous fumes be applied in larger quantities, and confined in the apartments to be disinfected a longer time. But he reports his experiments in full, and lets them speak for themselves. The net result of these tests is to show that some disease-germs escape even when the most effectual modes of disinfection practised at quarantine below New Orleans are resorted to, and that less than one-fourth of them are killed when the least effective method is used. It may be assumed that quarantine and city health officers everywhere will profit by the suggestions of this report, and that the public will be better protected in the future than in the past.

TUBERCULOSIS TRANSMITTED BY THE MILK OF A PHTHISICAL COW.

A remarkable case has been recorded by Denune, of Berne, in which an infant became infected with tuberculosis through the milk which had been obtained from a phthisical cow. The details of the case are as follows: An infant, aged four months, belonging to a family whose history was absolutely negative in regard to tubercular affections, died of tuberculosis of the mesenteric glands, a fact which was confirmed at the post-mortem examination. The glands alone contained the characteristic bacilli; the latter were not even to be detected in the intestinal mucous membrane, and no bacilli were found in any other part of the body. The child was fed with the milk of a cow which was especially kept for the purpose. The cow for the purposes of examination and inquiry was slaughtered, and a careful post-mortem made of its carcase. The left lung and pleura of the animal were found to be studded with tubercle, and in the tubercular nodules, bacilli were easily found. The milk was then submitted to a minute investigation, but bacteriological examination at first yielded negative results. Finally, however, tubercle bacilli were detected in portions of the liquid expressed from the deepest parts of the mammary gland. The case is an important one from several points of view, and claims attention by reason of its bearing upon the so-called hereditary transmission of tuberculosis. If, instead of a human infant, a calf had in a natural manner fed itself, with milk from its mother's udders, we can hardly conceive otherwise than that the calf would have similarly become infected with tubercle. Assuming such to have occurred, the case would obviously have been regarded as one of the hereditary transmission of tubercle. But taking the supposition that a woman suffering from phthisis suckles an infant, there seems to be no reason why the same result should not occur, and why, like the infant and the cow, to which reference has been made, the mother should not transmit the bacilli by means of her milk to her offspring. All this appears to be possible enough, and has, perhaps, even occurred in some cases without the fact having been proved by demonstration. — *Medical Press and Circular*, June 27th, 1888.

THE INEQUALITIES OF MEN.

M. LAPOUGE of Montpellier, has recently delivered before the Faculty of National Sciences in that town a series of lectures on inequalities among men, in the course of which he said that the political dogma of equality rests on hypotheses which are utterly false. He distinguished four social types among mankind, which are thus summarized it the *London Medical Recorder:* (1) The initiators, who show mankind the way into the region of the unknown, and who go in front. Restless and daring, with an intelligence which is at least equal to the average, men of this type do not travel readily along beaten tracks. New ideas are the breath of life to them. They spend their lives in new creations; they are often wrecked, but the true genius represents the most perfect form of this type. (2) Men of spirit, of intelligence, who, possessing no creative power themselves, yet carry out and perfect the ideas and discoveries of the first type, to which they are really the complement. (3) Men who, with much or little intelligence, can work only with others, who mistrust every new idea not accepted by all the others, but who seize it with avidity when their neighbors adopt it. If intelligent, these men are docile, but they dislike every change in routine, and they represent the dulness of the mass in the face of every reform. (4) Men of this type are not fit to attain even the smallest step in culture. Evidently every man cannot be classed under one or other of these divisions. In human societies clear lines of demarcation do not exist, but for general purposes the distinction is sufficiently evident. The superiority of a race or nation depends on the greater or smaller number of men of the first two classes. The race which is richest in the first type is the blonde dolichocephalic, and this has been the case even when the people among whom they lived were not of this kind. In Egypt, Chaldea, Assyria, Persia, and India, and even in China men of this type ruled. In the Greek and Roman world it was the same, and it is so still. In our own day the rank of a nation corresponds with the strength of the blonde dolichocephalic element. The Gallic and Frank elements which made France great were of this type, and it plays the same part in England, Germany, and America. Near these came the Semitic and Mediterranean races, who had reached a high grade of civilization when the blonde dolichocephalic peoples were still savages. The remainder of mankind must be reckoned the passive races. The brachycephalic races of Europe, the Celto-Slavs, rarely produce men of the first intellectual type. In the social changes of recent years brachycephalic men, who form the lower classes, have been elevated and brought forward, and herein, the lecturer thought, lies the great danger of the future deterioration of the French nation. The existence of the superior blonde dolichocephalic type is threatened by amalgamation with the dark brachycephalic and inferior races.

ARSENIC POISONING THROUGH THE MATERNAL MILK.

DR. BROUARDEL, Professor of Medical Jurisprudence at the Paris Faculty of Medicine, was lately consulted by the Tribunal Court on the question as to whether an infant of twelve months could have been poisoned by the milk of its mother in the case where the latter had absorbed arsenic. The following account of the circumstances which cause this inquiry is given by the Paris Correspondent of the *Lancet*. A man, having been accused of forgery with the intention of appropriating to himself the fortune of his wife and that of his mother-in-law, was at the same time suspected of trying to poison his wife, and having thus caused the death of his child, which the mother was suckling at that time. The child died with symptoms of cholerine a few days after the mother had herself presented analogous symptoms, such as diarrhœa, vomiting, etc. As it was during the hot season, these accidents did not excite attention. It was only after the the second choleriform attack, which occurred in November last, at the same time in the mother and grandmother of the child, that the husband was suspected. On the other hand, the wife declared that she had found in her husband's pocket, a white powder which was nothing else than arsenious acid. To resolve the question, Dr. Brouardel caused the coffin containing the body of the child, which had been buried about six months, to be brought to Paris. This body was completely transformed into cadaveric fat, and it was impossible to isolate the viscera from the other parts, so that it was submitted to analysis in its entirety. It weighed about two and a half kilogrammes, and contained five milligrammes of arsenic which did not proceed from the linen enveloping the corpse, or from the earth surrounding the coffin. It was necessary, in the second place, to know whether arsenic was eliminated by the milk. M. Gabriel Pouchet, an eminent biologist, had performed certain experiments in this direction, which was very conclusive. He caused a certain number of wet nurses, who were patients at the St. Louis Hospital, who were affected with skin diseases, to take a certain quantity of Fowler's solution (from two to twelve drops per day), and he was able to ascertain that under these conditions the milk of these nurses always contained a relatively considerable quantity of arsenic; thus the milk of one nurse who took in six days eight milligrammes of arsenic containing one milligramme of that substance to 100 grammes of milk. It must be added that with these doses the nurses and their infants do not appear to be affected by any accidents. But this does not prove that this would have been the case if the arsenic had been given at once in a single dose. In order to clear up this last point, recourse was had to experiments on female animals. This last series of experiments did not give conclusive results, because the animals presented a very variable susceptibility to arsenic, and the experimenter found it impossible to come to any conclusion concerning these experiments as compared with those performed on human beings. It is, however, evident, from these researches, that the lactic secretion is a means of elimination by predilection for arsenic, and that it is prudent not to administer this agent to suckling mothers. In the particular case under notice, in responding to the Juge d'Instruction, Dr. Brouardel stated that the body of the infant contained a suffcient quantity of arsenic to cause the death of a child of one year, and that this arsenic may possibly have had for vehicle the milk of the mother. This qualified conclusion did not seem to affect the defence or the accusation, and the husband was condemned to twenty years' hard labor.

Correspondence.

A REMEDY FOR SICK HEADACHE.

MILFORD, MASS., July 16, 1888.

MR. EDITOR,— I take for granted that many physicians in active practice would hail with pleasure a remedy that would meet and effectually relieve a majority of the cases of sick headache.

During the past five or six years I have used the following combination with good success.

R	Podophyllin	¼ grain.
	Citrate Caffeine	½ grain.
	Sub-Nitrate Bismuth	3½ grains.

M. One dose to be used when the headache is approaching. Repeat in two hours if needed.

Messrs. John Wyeth & Bro., of Philadelphia made compressed pills for me from this formula (making the pills half weight), of whom any physician can get a supply by ordering.

This combination has served me in practice so well that I desire to give others the benefit of it. Yours truly

JEROME WILMARTH, M.D.

— *Fliegende Blätter* has a comment on the so-called "Study of Objects" which is not without its application in the medical profession. *Professor:* "How many legs have insects?"— *Candidate:* "65 per cent. of insects have no legs at all, 11 per cent. have one, 14 per cent. two or three, 10 per cent. four or five, but none six."— *Professor:* "How in the world did you get this answer?"— *Candidate:* "By carefully examining the collection belonging to the University."

REPORTED MORTALITY FOR THE WEEK ENDING JULY 7, 1888.

Cities.	Estimated Population for 1888.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 3,022: under five years of age 1,519; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 964, consumption 298, acute lung diseases 137, diarrhœal diseases 711, diphtheria and croup 84, measles 27, scarlet fever 34, whooping-cough 32, typhoid fever 28, cerebro-spinal meningitis 19, malarial fever 15, small-pox five, puerperal fever three. From scarlet fever New York 23, Philadelphia four, Chicago two, St. Louis, Boston, Cincinnati, Pittsburgh and Lawrence one each. From whooping-cough, New York eight, New Orleans seven, Chicago and Baltimore four each, Philadelphia, Boston and Charleston two each, St. Louis, Washington and Haverhill one each. From typhoid fever, Philadelphia nine, Chicago six, New York four, Cincinnati and New Orleans two each, St. Louis, Baltimore, Pittsburgh and Lawrence one each. From cerebro-spinal meningitis, New York four, Baltimore three, Chicago, St. Louis and Cincinnati two each, Pittsburgh, Nashville, Worcester and Lynn one each. From malarial fever, New Orleans six, St. Louis five, New York two, Philadelphia one. From small-pox, Philadelphia three, New York and Nashville one each. From puerperal fever, Boston, New Orleans and Pittsburgh one each.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending June 23d, the death-rate was 15.5. Deaths reported 2,794: infants under one year of age 636; acute diseases of the respiratory organs (London) 184; whooping-cough 80, diarrhœal diseases 48, fevers 33, diphtheria 29, measles 25, scarlet fever 24, small-pox (Sheffield five, Preston two, Manchester and Leeds one each), 9.

The death-rates ranged from 9.9 in Nottingham to 24.3 in Preston: Birmingham 14.3; Bradford 12.5; Halifax 10.3; Hull 15.0; Leeds 15.0; Leicester 17.8; Liverpool 16.0; London 14.5; Manchester 22.5; Newcastle-on-Tyne 19.7; Oldham 18.1; Sheffield 15.7; Sunderland 16.2.

In Edinburgh 11.9; Glasgow 22.8; Dublin 20.7.

The meteorological record for the week ending July 7, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, July 7, 1888.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 7, 1888, TO JULY 13, 1888.

DEWITT, CALVIN, major and surgeon, United States Army. Leave of absence extended one month. S. O. 59, A. G. O., July 11, 1888.

BANISTER, WILLIAM B., lieutenant and assistant surgeon. Leave of absence extended twenty-seven days. S. O. 157, A. G. O., July 9, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING JULY 14, 1888.

MARTIN, WM., assistant surgeon. Ordered to Marine Rendezvous, San Francisco, Cal., and to attend officers of the Navy and Marine Corps not otherwise provided with medical aid.

AUZAL, E. W., assistant surgeon. Detached from duty at Marine Rendezvous, San Francisco, Cal., and special duty there and ordered to the Naval Academy.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JULY 16, 1888.

BAILHACHE, B. H., surgeon. To proceed to Delaware Breakwater Quarantine Station as inspector. July 6, 1888.

FESSENDEN, C. S. D., surgeon. Leave of absence extended thirty days on account of sickness. July 14, 1888.

PURVIANCE, GEORGE, surgeon. To proceed to Chattanooga, Tenn., as inspector. July 6, 1888.

SAWTELLE, H. W., surgeon. Granted leave of absence for twenty-three days. July 9, 1888.

MCINTOSH, W. P., assistant surgeon. To proceed to Galveston, Texas, for temporary duty. July 14, 1888.

PETTUS, W. J., assistant surgeon. Granted leave of absence for thirty days. July 16, 1888.

OBITUARY. DR. J. MILNER FOTHERGILL.

Dr. J. Milner Fothergill, the well-known English author of numerous and popular medical works, died suddenly the latter part of June. He was born on April 11, 1841, at Moreland, in Westmoreland. At an early age he was apprenticed to his father, who was also a medical man. He qualified in 1865 at Edinburgh, and for a while practised in his native village. Some years later he took the post of senior resident medical officer of the Leeds Public Dispensary. It was at about that time that he wrote his well-known essay upon "Digitalis, its Mode of Action and its Use," which gained for him the Hastings Gold Medal of the British Medical Association in 1870 He subsequently spent some time in Vienna and Berlin, studying his profession, and it was at the latter place that he wrote his work which passed into a second edition in 1879, "The Heart and its Diseases, with their Treatment, including the Gouty Heart." On his return to England in 1872, he took the membership of the Royal College of Physicians of London and settled down as a consultant. Sometime later he was elected junior physician to the West London Hospital, a post he resigned in 1881. In 1875 he was elected on the Staff of the City of London Hospital for Diseases of the Chest, at Victoria Park, a post he retained up to the last. In 1876 he brought out his best-known work, the "Practitioner's Hand-book of Treatment," a second edition of which was called for in 1880. After this date he carried out some original researches on the antagonism of drugs which paved the way to the employment of atropin as a remedy in cases of opium poisoning. His essay on the result of his observations gained for him the Fothergillian Gold Medal of the Medical Society. He was also elected an Associate Fellow of the College of Physicians of Philadelphia in 1879, and later, was made an honorary M.D. of Rush College, Chicago. More recently he wrote a very entertaining and instructive work on "Vaso-Renal Change *versus* Bright's Disease."

An English contemporary, from which we have derived the above facts, says of him: "The deceased was at all periods of his life an indefatigable worker. He was, at the same time, a practical physician and an accomplished *littérateur*. Bluff in his manners, his taste for sarcasm sometimes offended those who did not know him well enough to recognize the hearty good-nature that underlay the rough outside envelope. He was hospitable to a degree, and visitors from across the Atlantic knew no greater treat than to pass an evening with him enjoying the brilliancy of his conversational powers and the frank laughter with which he greeted the witticisms of others. His books were characterized by the same sound common-sense and *bonhomie* as his observations, and were unusually light reading for technical works. He was at least as much appreciated in America as at home, and his articles and books always commanded a favorable reception. Probably his last 'outing' was his trip to Bournemouth on the occasion of the opening of the new piece of railway. He was then far from well, but managed to make a very telling speech at the luncheon. Dr. Fothergill was a martyr to gout, and was enabled to treat of it *en connaissance de cause*. His burly figure will be missed by a large circle of friends both inside and outside the profession."

OBITUARY. DR. A. Y. P. GARNETT.

Dr. A. Y. P. Garnett, of Washington, D. C., dropped suddenly dead at Rehoboth Beach, Del., on Wednesday the 11th inst., in the sixty-eighth year of his age. He was born in Essex County, Va., and was graduated from the University of Pennsylvania, Department of Medicine, in 1841, in which year he was appointed an assistant surgeon in the United States Navy, in which he served until 1848, when he settled in Washington. At the outbreak of the civil war he entered the Southern army as surgeon, returning to Washington at the close of the war, where, having been the physician of the late W. W. Corcoran, he acquired a large practice, especially among the Southern residents of that city. His marked Southern sympathies are shown by a recent remark made not altogether in jest, that the only two unreconstructed rebels now left in the country were Jefferson Davis and himself. From 1856–61 and 1866–70 he was professor of clinical medicine in the National Medical College of Washington. In 1870 he was appointed emeritus professor, which position he held at the time of his death. He took an active part in organizing the Ninth International Medical Congress, and was elected president of the American Medical Association in 1887.

INQUIRY INTO THE INFLUENCE OF THE TEMPERATURE OF THE AIR ON THE DEATH OF INFANTS FROM DIARRHŒAL DISEASES.[1]

BY DR. MEINERT, OF DRESDEN.

GENTLEMEN: It is a universally acknowledged fact proved by statistics, that the mortality of infants is chiefly due to diseases of the intestinal canal, and it is also universally acknowledged that the increase of mortality of infants owing to diarrhœa is connected with the elevation of the temperature during the summer months.

It is known, that epidemic summer diarrhœa of infancy appears only in those places where, in the summer months, the average temperature by day rises above 16° C. (59° F.), that large cities chiefly suffer from it, that infants at the breast of mother or wet-nurse are less subject to it than those fed artificially. A certain uniform correspondence between the temperature of the air and mortality from diarrhœal diseases has been observed in certain places. There is no lack of hypotheses as to the origin of the summer diarrhœa of infants, but there are no personal observations which can enlighten us as to the real nature of this disease, which has increased to such an extraordinary degree.

Statistics, which have often proved successful in deciding medical problems, are no guide in these cases. The causes of death assigned in the public records, during the summer months, in referring to children under one year of age, are most unreliable; for not only is a medical certificate utterly wanting in the majority of cases; but even when such a certificate exists, there is a want of unanimity as to the name of the disease.

One special cause of the prevailing confusion, is the universal application of the term "convulsions," which we find most frequently in official reports, not only to such cases as were without medical assistance, but to those numerous cases where diarrhœa of infancy was complicated with convulsions.

The diagram laid before you, which gives a clear idea of the cause of death among infants in Dresden during the different months of the years beginning in 1881, shows how the increase of deaths in the height of summer, is every year attributable to the great frequency of convulsions and diarrhœa.

If we now undertake to examine etiologically the influence of certain causes on the disease, we shall be compelled not only in cases of death from diarrhœa (cholera infantum, cholera morbus), but also in cases of supposed "convulsions," to inquire exactly into the character of the disease in question. This is only possible by direct inquiry in the families where such deaths have taken place.

According to the data I have been able to procure from the Registration Reports concerning single cases of death in Dresden during a period of eleven weeks, July 11, to September 25, 1886, in 796 cases of infant mortality (under one year of age), 281 were attributed to convulsions, and 382 to diarrhœal diseases under various names. Of these 663 cases 59% were testified by a physician. In 90½% of the cases the efforts to determine the causes of death were successful mainly owing to the cöoperation of my colleagues Drs. Hecker, Schottinir and Gilbert, and almost all the medical men under whose treatment the deceased children had been, encouraged me by their permission to anamnestic researches.

Further research proves that 36 cases of *genuine convulsions*, and 580 of *diarrhœal diseases*, had occurred. Five hundred and nineteen papers, each containing 30 questions were returned to me, with the chief points well filled, the object being by this means to make a definite statement as to the clinical features. The diarrhœa was sometimes unaccompanied by *vomiting*, very frequently with convulsions; of these latter it was, of course, only possible to obtain exact information concerning those of the clonic form, about 20% of the cases. We counted 35 cases of *chronic (gastro) intestinal catarrh*, and 444 of *acute diarrhœa* (cholera infantum); of the children carried off by these diseases, 71% had till then preserved healthy digestive organs, and 54% were healthy in every respect.

On this chart I have noted each case with its number; in the lower diagram, the day the illness commenced, in the upper, the day of its fatal termination. Homonymous numbers (those referring to the same case) are joined by a line, so that the duration of each separate illness can be easily observed. The curved lines over the diagrams gives the mean daily temperature in the open air, the height of the barometer, and the average relative humidity of the air, above these are noted the velocity and direction of the wind, the rainfall and thunderstorms.

You see, gentlemen, to what extent a rise of temperature augments the number of cases of sickness as well as the number of deaths. *Pressure and humidity of the atmosphere, rainfall* and the *direction of the winds*, have less power to disturb the parallelism between increased illness and the temperature of the air, than has been hitherto supposed; and the *velocity of the wind* modifies it to a great extent.

A higher degree of temperature combined with high wind, is not dangerous, but moderate temperature without wind, produces a considerable increase of sickness and death. Most of these cases occur on hot days with little wind, and most cases of sickness are found together with these unfavorable conditions of the weather, or they follow immediately upon it. There are days, when the numerous cases of death coincide with the most unfavorable condition of the weather, but often they follow also with longer intervals (of a week or so). This circumstance is described by the lines representing the illness. In the average, the infants died 7½ days after the day on which they were taken ill with diarrhœa; 26 under 24 hours of sickness, 49 on the second day, 54 on the the third day of illness. Of 444 infants, only 27 lived longer than a fortnight from the time of being taken ill.

The greater the heat, and the stiller the wind, the quicker the development of the sickness, and its fatal termination will be.

You will see that the vertical lines which denote the cases, which terminated fatally the same day the illness commenced, occur only in the hottest and most sultry days.

If the weather is the same at the end as it was in the beginning of the eleven weeks, the mortality is, notwithstanding different; namely, lower in the beginning, and higher at the end. This is to be explained partly by the larger amount of accumulated heat,

[1] Lecture delivered in the Hygienic Section, at the sixtieth meeting of German naturalists and physicians.

stored up in the walls of the houses during the height of the summer, and partly by the greater number of sick children, which increased from week to week — as my diagram shows. The 3d, 14th and 16th of September, were the days on which the greatest number of deaths from diarrhœa occurred during the whole course of the epidemic (19, 18 and 21 cases); these however, include cases of illness which occurred during the previous weeks. I refer to those infants of whom, as our anamnestic researches show, one part were already on the way to recovery, and probably would have recovered, if the intense heat of July, which produced diarrhœa had not returned in September.

The results of the census of December 1, 1885, enabled me to make inquiries into the conditions under which the infants in Dresden died of diarrhœa during the eleven weeks recorded.

Among 246,088 inhabitants of Dresden, (including the military establishments) there were 5,893 (23.88%) children, less than twelve months old, according to the census of December 1, 1885; of this number (not including doubtful cases) 580 died of diarrhœa (cholera infantum), with or without convulsions, between the 11th of July, and the 25th of September, that is to say, of the girls 9.18%; of the boys 10.15% (about the same percentage of both sexes, as in the other months of the year). Of these children, 15.7% were illegitimate; 60.8% belonged to the working classes, 23% to the middle classes, ½% to the higher, and more educated classes. In Dresden, 10.22% of the children living on the right bank of the Elbe died, while on the left bank (notwithstanding that the mean temperature was 2.13%C. [17.46° F.] higher during the weeks recorded than on the right bank) only 9.59% died. In the eleven districts, the percentage of deaths fluctuated between 4.6% and 13% among infants under twelve months old; the relative number of infants was not always in proportion to these deaths; there were districts, with a considerable population of children, where there were many deaths, and again other districts, containing the same population, where comparatively few deaths occurred. Illegitimate infants, among whom the mortality is greater in Dresden as well as in most other places (judging by the year's record) were attacked by fatal diarrhœa less than legitimate children. The percentage of deaths at different times during the first year of infancy, and the number of deaths from gastro-intestinal diseases, differed in the cooler seasons from that in the hot summer-months. There is also a difference in the number of deaths in the various stories of the houses.

All these peculiarities, paradoxical as they appear at first, were confirmed by the observations renewed in the four abnormally hot weeks in 1887. (We speak of the deaths occurring in Dresden on the left bank of the Elbe, among children in their first and second years.) But in 1887 (in 141 cases), the average duration of the illness was shorter (three and one-half days), the number of the rapid cases larger, (for instance, death taking place on the first day in 14% of all cases, against 6% the preceding year). In the middle classes the average number (32%) was larger; among the working classes far less than in the year 1886 (only 53.19%). For 1887 the cases complicated by convulsions were far more frequent.

The direction in which I had to continue my investigations was thus clearly indicated. First of all the *dwellings* in which deaths had occurred, had to be examined.

I found that *generally deaths by summer diarrhœa occurred only in those dwellings in which, by the influence of a high atmospheric temperature, a still higher temperature indoors had developed*, in consequence of insufficient natural ventilation. I observed that deaths occurred more frequently in dwellings exposed to the heat of the sun to which winds had scarcely any access. The greatest relative number of deaths occurred in the parterres and first floors. (These were exposed not merely to the direct heat of the sun, but also to the heat produced by the reflection of the rays of the sun from the soil.) In the underground dwellings (souterrains) which are very little exposed to the rays of the sun, there was the smallest number of deaths.

Compared with the total number of children under one year of age, living the first of December, 1885, in each of the various stories of dwellings, there died of diarrhœa during the weeks above mentioned:

	1886 (580 cases).	1887 (134 cases).
Underground	3.98 per cent.	2.44 per cent.
Ground Floor	12.78 "	4.48 "
First Floor	10.70 "	3.03 "
Second Floor	9.13 "	2.36 "
Third Floor	8.18 "	2.70 "
Fourth Floor	9.18 "	3.69 "
Fifth Floor	11.27 "	1.61 "

To gain an exact insight into the influence of dwellings on the diarrhœal diseases of infants, the first floors where deaths had occurred in 1886, were examined. The dwellings on the first floor, being inhabited by the better classes, where poverty could have no influence, were the most suitable for the purpose.

The temperature of these dwellings, which were examined in July and August, 1887 (one meter from the floor), was found higher than the outside temperature in the shade by 3.60° C., (29.52° F.), to 14.40° C., (56.64° F.), on an average of 8.59° C., (42.95° F.). Evidently great obstacles existed which prevented the proper entrance of atmospheric air to these dwellings.

Only one child died in a detached house, the other houses where deaths occurred were in broken rows or surrounded by buildings. It was only in ten houses that it was possible to have a thorough draught from one side to the other. The fact of living in close proximity proved to be of importance only in those cases where there was a lack of ventilation. In the dwellings of the first floor, where deaths occurred, we found on an average, in the bed-rooms 12.72 cubic meters of air for each person. In the houses of the Johann Meyer-Strasse, which have been built for workmen by the City Board, and which escaped the disease, a child has, on an average, to be satisfied with 4.57 cubic meters of air in the bed-rooms. But these houses are not enclosed by other buildings, and the rooms can be exposed to strong, beneficial currents of air.

In that part of Antonstadt which consists chiefly of villas, only three deaths occurred, although there are 11 streets and 2,921 inhabitants, among them being fifty children under a year of age. These deaths occurred only in one house (Schillerstrasse 63), a house which by its wings and backbuildings forming narrow courts, is the most unhealthy of all the dwellings in that quarter.

In dwellings of equal cubic measurement — *ceteris paribus* — there were the greatest number of deaths

in those with low rooms. (Rooms with higher ceilings allow better ventilation through the walls.) In the dwellings where deaths occurred, the rooms on the first floors were 2.78 meters high, against a height of 3.23 meters in the workmen's houses before mentioned.

Gentlemen, the plan of the city which I here lay before you shows by different colors the average proportion of deaths in each single street (compared to the total number of infants under twelve months who were living on these streets). You will never find proportions which cannot be explained by the condition of the dwellings and the density of the population.

Sometimes I doubted whether the relations I found existed in every case. But I found again that the observed dependence existed everywhere. The great mortality, for instance (15.78%), in Schillerstrasse, which is a superior part of the town and like a garden, was solely due to the three cases in the house No. 63. In the Oppel-Suburb you see three streets close together, in which the deaths differ greatly in number. In Hechtstrasse there were 18.49%, in Kieternstrasse 2.50%, in Johann Meyer-Strasse 0.00%, although the population of all these three streets consists of the same class of workmen. But Hechtstrasse is built on very low ground in close terraces with lateral and back-buildings; the Kieternstrasse lies high with semi-detached houses, and in Johann Meyer-Strasse (although the drainage is indifferent), we find only detached houses of the working classes, consequently surrounded on all sides by the open air.

The next question was, whether among the whole number of children, living in unhealthy houses, we could discover a reason for individual causes, which might explain the fact that one portion of the community should be attacked by fatal diarrhœa while the rest escaped.

Physicians are accustomed in such researches to make a distinction between legitimate and illegitimate children, and they are right, because by the unfavorable conditions of their nourishment illegitimate children are more likely to be subject to affections of the stomach and intestines.

It is a remarkable fact that, as I have mentioned before, in the year 1886, *during the eleven weeks*, beginning July 11th, a relatively smaller number of illegitimate children died than legitimate (namely, 6.82% illegitimate out of 1,334 living illegitimates, and 8.82% out of 5,534 living legitimates), against 21% deaths of illegitimate and 16% of legitimate children *in the whole year*. This may have been mere chance; but, as the reports proved, the case was the same in the year 1887. If we go back ten years and compare the relative proportions of the third quarter of every year with the other quarters, we find, as you may learn by this diagram, that this strange fact was not observed until the year 1883, and then somewhat suddenly. At that time people began to take more interest in the matter than had been the case formerly. Up to that period illegitimate children had been under the control of the government police. According to an order issued by the Saxon parliament the town was now charged with the inspection of these children, and this duty is since then performed in the best manner possible. Only such women are permitted to take charge of illegitimate children (and then only of two at a time), whose dwellings have been declared by the inspector of the local Board of Health to be healthy. By this reason we recognize the cause of lower mortality among illegitimate children; it is the more favorable condition of dwellings which in Dresden are selected for illegitimate children, whilst legitimate children of workmen are condemned to live in the worst imaginable dwellings.

The greatest contrast, however, consists between children fed in a natural manner and such as are brought up artificially; this has been observed whereever unusual mortality from summer diarrhœa prevails.

There were in Dresden, out of 479 children in 1886, mentioned above, only 19 nursed at the breast, none of them more than three months old. In 1887, of 123 children, of our report, nursed at the breast only 5, and not one more than four months old. The only nourishment, or at least the principal food, of almost all the other children had been cow's milk. (According to researches made *ad hoc* — among some hundreds of families of workmen, in reference to their children of one, two, three, four, five, etc., months, 65.07, 60.26, 49.78, 38.94, 35.75, etc. per cent. were nursed by their mothers.)

The fact of the existence of a noxious influence which explains the dangerous condition of certain dwellings, as well as the little chance to escape for children brought up by hand, is a fact of the highest importance for the etiology of cholera infantum. Hitherto, there has been a lack of authentic criterions for the different hypothetic arguments which treat of the origin of our disease.

Why do infants at the breast have an advantage even in the most unhealthy dwellings, and why do children brought up by hand very seldom die of the summer diarrhœa, in favorable dwellings, although at other times disposed to it to so great a degree?

If I were to indicate the noxious qualities, which give a special characteristic to the dwellings in which the infant died, I should say, there was partly an impure air by the exhalation from human beings. However, too great a stress must not be laid on this, because similar conditions and circumstances are found in winter without producing the characteristic summer disease.

Far more important appears to me the consideration that the *climate in the dwellings* where the children died, even when the temperature was moderate, was, by an exceedingly low measure of ventilation, *such as to hinder the functions regulating the heat of the body.*

Flügge, in his valuable researches on "Das Wohnungsklima fur Zeit des Hochsommers"[2] has already drawn attention to this danger.

If all the remedies are at hand which the regulation of heat affords at the time of its greatest requirements, no very serious danger for the balance of heat is threatened by the sun of our latitudes, not even in the worst conjunctures which are possible in our dwellings. The most important of these remedies is the *increased consumption of water*. This consumption of water by the *infant at the mother's breast* is regulated in the most practical manner possible, by an increased consumption of water by its nurse. (I have made this self-regulation the object of a special series of examinations.) But it is different with an *infant brought up by hand*. In hot weather it will drink — if the intelligence of the mother does not put a stop to it — in-

[2] Beiträge für Hygiene. Leipzig, 1879.

creasing quantities of milk, and as the milk is of the same concentration as usual, the infant takes an *excess of substantial food.*

By this the *production of heat of the body will be increased*, instead of, as is the case with an infant at the breast — of being diminished in the warm season.

This happens the sooner, as the digestive organs of the infants are the more normal. (Indeed there were among those 444 children, mentioned in the first part of my lecture, that died from summer complaint 71 per cent. with previously healthy digestive organs.) Other children will catch dyspepsia by an over-filling of the stomach, and will then take in less water than the high temperature of the summer requires.

In the one case as well as in the other, there is an *increase of the temperature of the body* under certain external conditions preventing the discharge of heat of the body.

As a matter of fact thermometrical observations which we made on the months of July and August, 1887, in presumably unfavorable dwellings, on a great number of infants, proved that a feverish increase of temperature of the body very frequently occurred.

Here in my chart you see some curves referring to infants whose temperature was taken (*in ano*) three times daily for weeks together. By these curves you can recognize the increase and decrease of temperature out of doors, and that of the essentially higher temperature in the dwellings. Two of the graphic charts are especially interesting. In both cases, the indoor temperature of the air increasing rapidly after a prodromical fever of a few days, together with a temperature (*in ano*) of 38.8° C (102.84° F.) *a typical cholera infantum sets in*, complicated in the one case by convulsions and ending with death.

Gentlemen, we have now arrived at the point where, according to my opinion, the problem lies.

Is the prodromal fever of the children's sickness only produced by *accumulation of heat* of the body, and in this case, what is the relation between this fever and the typical affections of the digestive organs? or have we, from the very beginning, to deal with the invasive fever of a *zymotic disease*, the producer of which is only developed, when just these dangers of dwellings and foods are united, which we recognized as the genetic conditions for producing cholera infantum?

My modest contributions in solving these questions range naturally with my clinical statements in the cases referred by me. But this appears to me to belong less to the province of the hygienic section of this Congress and therefore I intend to conclude my report on this subject in the section for diseases of children.[3]

The influence of the above mentioned conditions of dwellings in the hottest days of summer shows itself by the *different degrees of danger for the different ages of the children.*[4] The highest mortality prevailed among the children under six months. Their greater danger is partly explained by the special nature of their digestive organs which disagree with artificial food; partly by the perspiration which is so very important to the regulation of heat and which is only developed after the first three months of life; partly by the bad habit,—customary in Saxony— of keeping children of this age under thick covers even in the greatest heat, thus forcibly preventing the movements of the limbs by tight clothes. From the sixth month the mortality decreases rapidly so as almost to disappear in the second year, when children acquire the most important faculties of free movement and of speech, as a preventive against suffering from excessive heat.

Now, gentlemen, I request you to glance at my graphic chart, which shows the monthly rate of mortality amongst children in the larger towns of the European continent and the United States of North America (the percentage being taken from 100 infants born alive), as far as serviceable reports were at my disposal. You see, in looking at the map of Europe, how the mortality of infants in the summer months constantly decreases towards the south from Berlin to Rome, in spite of the increasing temperature towards the south. Without doubt one chief cause is, that towards the south of Europe you find more mothers suckling their infants. The houses which in our own country are more adapted to shelter us from the inclemency of a cold climate, as well as the treatment of children, are in the South in better accordance with the requirement of a warm climate.

I hope, gentlemen, soon to be able to supply the omissions you will have noticed in my statement of to-day, by a complete publication of my material and my researches. Until then, I will permit myself to postpone my thanks to those colleagues and officials in government and municipal service by whose kind coöperation I have been enabled to work thus far.

[3] See short report in Jahrbuch für Kinderheilkunde, N. F. xxvii, 3.

[4] Compared with the total number of children living July 1, 1886, in the 1st, 2d, 3d, 4th, 5th, 6th, 7th, 8th, 9th, 10th, 11th, 12th months of their age, the percentage of deaths from diarrhœal diseases was 14.40, 13.10, 13.07, 12.41, 12.42, 8,63, 6.06, 6.09, 4.05, 3.52, 3.32, 4.12.

INVETERATE HEADACHE, WITH CASES.[1]

BY HAMILTON OSGOOD, M.D.

To write upon persistent and oft-recurring headache, is nearly as discouraging as the attempt to overcome it by treatment. It is an affection which either yields to no remedy whatever, or, if it be relieved, is sure to return as soon as the effect of the panacea has disappeared. If not of this inveterate character it is very frequent, is intractable while it lasts, and so capricious, that although it may yield to a given method of relief upon one occasion, upon another the treatment is not of the slightest avail. This discourages the patient and annoys the physician. If the latter be a routinist he is embarrassed. He plies his anti-neuralgics. They achieve little or nothing. Sometimes he feels encouraged; generally he is baffled. Strange as it may seem he makes no effort to discover a hidden cause for the pain. To him headache means neuralgia, and the remedies he applies are simply those which report says are efficient in such cases.

Occasionally, among wiser and more thoughtful physicians, there is a degree of indifference, a careless resort to a well-thumbed prescription which generally fails. The case is uninteresting. It presents no stimulus to the physician's mind. In short, he neglects the patient and wins what he may deserve, but which is not true of him, a reputation for ignorance.

The common, the non-perilous ailments of our pa-

[1] Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, May 9, 1888.

tients are apt to be superficially treated. Headache is a plague to an indolent medical man. He regards it as of little moment, and treats it accordingly. To the patient, however, the ailment is a serious matter, depriving him as it does of power in practical life, of enjoyment of vacation, of comfort at home. It entails annoyance to others, for it renders the sufferer irritable, unjust and uncompanionable. If he be not relieved when he might be, the physician naturally deserves blame for an evil of wide extent.

In the nerve-tissue concerned in the form of pain in question, there seems to be almost intelligence and reasoning power. Unfortunately, this is shown by the incessant endeavor of this tissue to reassert itself. Pathologically sensitive nerves seem never to forget their capability of creating suffering. One might say they were ever on the alert for lack of vigilance on the part of the patient; that they constantly lurk for opportunity, for, no sooner are they quieted by the physician's skill than they start up armed with new vigor in their diabolical ability to torture humanity. Their arts are hydra-headed and woe betide the object of their wiles if he for a moment relax his self-defence. He may forget but they never do; on the contrary, the more careless he, the more active and energetic are they.

It is no wonder then that chronic headache is indifferently treated by so many physicians. The very persistence of the pain too often destroys the interest of the medical attendant.

Inveterate headache may be relieved by one or more of the scores of internal and external remedies, but these merely wither the fruit without touching the root of the evil. Indeed, the management of this affection is so empirical that it recalls Voltaire's reflection upon the practice of medicine, which he said consisted in: "Putting medicines, of which we know little, into a body of which we know nothing." No sooner does a form of treatment promise success in a patient, whose look and daily history indicate that at last the headaches have yielded, when like a thunderclap, a new series of attack appears, and the course adopted and heretofore efficient, becomes inert.

As an illustration: A lady, single, aged fifty-five, has suffered from intense headache since her youth. She has had every variety of treatment; has consulted many physicians. Remedies which on one occasion relieved her failed utterly on another. Change of climate was extremely beneficial during one year. On returning to the same locality the following year her headache was incessant. She is known among her friends as a victim of pain and has had every reason to feel profound discouragement. My first professional interview with her was during an attack of headache, in which, as is usual with her at such times, she seemed nearly unconscious from suffering. I was merely asked to relieve her by a subcutaneous injection of morphia, which I did, using one-half grain. Subsequently, I was requested to take charge of the case. A careful examination gave me the following information: The patient was well-nourished; appetite generally good; bowels in normal condition; her face showed the exhaustion caused by chronic pain; the menstrual periods (now passed) had always been regular, and, save that a headache was apt to follow them, free from annoyance of any nature. Her headache occasionally extended to the left side of the cranium, but was almost wholly confined to the right side and never took the form of clavus. The onset of pain, however, was not peculiar to the menstrual epoch, but occurred irregularly at other times, and so frequently that the patient was never sure of being able to keep any engagement whatever. "Pain is the prayer of the nerve for healthy blood," says Romberg.[2] During the thirty years of her experience of pain, this lady has taken every sort of tonic and every variety of blood-making food. The wise adage, "Eat when you are hungry but not so long as you are hungry," has been carefully observed, as have also the ordinary laws of health.

Sudden changes of weather have always given her great discomfort. This may be explained by Wright's[3] computation to the effect that a change of one inch in the barometer increases or decreases the atmospheric weight which the body of an average man sustains—by 1,080 pounds. "The results in periods of great weather fluctuations are headaches and even apoplexy." In my patient it is easy to imagine the painful effect of the abrupt oscillations in the circulation, which would occur under such conditions.

The headaches I found to be invariably preceded by flushing of the right ear, the color deepening, as the pain appeared, to a livid hue. A little later the left ear became flushed but never took on the darker color of the right.

This anomaly in the circulation led me to examine the heart. I found it free from organic lesion, but the first sound was weaker than the second, and both sounds as well as the character of the heart's impulse indicated lack of power in the cardiac muscle. This explained the temperature of the hands, which were invariably cold, and caused me to suspect that the lividity of the right ear during an attack of pain and the deeper co-existing color of the right face, as compared with that of the left, were due to weak heart and habitual lack of vaso-motor energy in the bloodvessels of the right side of the head. This, I argued, was a logical accompaniment of the persistence of pain in this side, and probably showed a chronic dilatation, or at any rate weakness in the walls, of the vessels of the right side, and which became apparent whenever the irritation of pain reflexively lessened the energy of the heart. During an attack, I further argued, these vessels probably dilated and since "vessels of the brain are not supported by pressure of surrounding elastic muscles, and have, moreover, a less powerful construction, than have bloodvessels elsewhere,"[4] this temporary dilatation of weakened vessels created a local obstacle to the onward flow of the blood, and hence the increasing deeper hue of the visible tissues of this as compared with the left side of the head and face.

The stagnation of the blood-current is naturally followed by an accumulation of carbonic acid, and in consequence by an exacerbation of pain. A good illustration of this local condition of the circulation may be seen in the purple outlines of the blood-vessels of a drunkard's nose. Here the vaso-motor energy is permanently deadened by alcohol, and we see the constant presence of carbonic acid. In the patient in question, however, the local impurity of blood disappears so soon as the pain and its reflex effects upon the heart cease.

[2] Nerven Krankheiten.
[3] On Headache.
[4] Wright on Headache.

In behalf of my theory allow me to digress for a moment in order to relate the most striking instance of neurotic reflex which has ever come to my notice. Some years ago I was called to a lady who was suffering from severe pain in the right ear. I had frequently relieved this ear of large masses of wax, and the patient rightly suspecting the cause of the pain, had vainly tried to clear the ear in the usual way. When I reached her house the lady told me she was also in great discomfort from a delayed menstrual period, now eight days overdue. It required fifteen minutes of time and copious injections of warm water to free the patient's ear from a very large mass of cerumen. The relief was immense, and, moreover, before I left the house the *period had appeared.*

It is not strange then that great pain in the head reflexively will lessen the power of the heart, and I feel very confident of the correctness of my argument in the case in question. After writing the foregoing, I happened to find in Anstie's clever book on neuralgia, the following remark: "muscular viscera which are composed of unstriped fibre, like the intestines, or of a mixture of striped and unstriped, like the heart, are probably very liable to a secondary paralytic influence from certain special neuralgias."

Still I was no nearer to a discovery of the original *cause* of the headaches. As to the quality of the pain I may safely repeat Begbie's words in relation to a similar case quoted by Day, in his book on headache: "It was not nervous, nor hysterical; it was not inflammatory, nor congestive; it was not anæmic; it was not dyspeptic; it was not of a rheumatic, nor of neuralgic character; it was not periostitic; it was not periodic." Finally, something in the general look of the patient, nothing positive, there being no especial symptom which could be named, suggested gout. The patient denied all knowledge of any case of this ailment in her family, but a careful inquiry into the family history revealed the fact that in several of her ancestors gout had existed. I at once determined to test this possibility, and took with me a quantity of the patient's urine for examination.

Previously, however, I ordered tincture of strophanthus in doses of four drops which I subsequently increased to eight drops, three times daily. I may say here that even before I adopted any other form of treatment, so soon as the cardiac tonic began to show its effect in a relatively stronger first sound of the heart, the headaches became less intense in character the discoloration of the right ear appeared less frequently, and when it did appear, was far lighter in hue. This was the first proof that the headaches were partially due to weak heart.

In examining the urine, I did not make a quantitative analysis for the uric acid present, but did find the fluid intensely and unusually acid, and that the specific gravity was 1,034. This, in the absence of albumen and sugar, confirmed me in my suspicion of the existence in the patient of a gouty tendency.

[In a lecture upon gout, Trousseau relates a case of headache which puzzled him extremely. This was in the early days of his practice. After a long period of doubt and insufficient treatment, the case was cleared up by a frank onset of gout, in reference to which Trousseau makes the interesting remark. "I did not then know that *gout* and *migraine are sisters.*— *Clinique Médicale*, Vol. III.]

Prescribing the bi-carbonate of soda in scruple doses, three times daily, the urine soon became moderately acid, the specific gravity fell to 1,024 and during the following six months, not only did the headaches become very infrequent but when they appeared the pain, save in two instances, was not acute.

Meanwhile, under alternate use of the tinctures of strophanthus and digitalis, the circulation of my patient had improved to such a degree that the hands and feet became habitually warm, her face lost its expression of exhaustion, her eyes brightened and she looked years younger than when I first saw her. This change corresponded with a steadily increasing power in the first sound of the heart which was now stronger than the second sound. During this interval, I substituted Buffalo lithia water (spring No. 2) for the soda, and the patient became more comfortable than she had been for several years, only two headaches of moment occurring during these six months.

This period of truce was then suddenly interrupted by onset after onset of intense headache, which, however, to my great relief, I soon found had their origin in the suppurating pulp of a molar tooth, so that they did not disturb my diagnosis of gouty headache. The tooth was soon relieved but the cranial pain held on. Antipyrine quieted the headache but caused unbearable nausea.

Just then appeared in *La Semaine Médicale*, Germaine See's recommendation to give with antipyrine, an equal bulk of the bi-carbonate of soda as a certain means of avoiding nausea. This proved a success, and disposed of all tendency to nausea in this case and several other cases. In the patient in question, however, the drug soon became inert. The caffeine, bromo-caffeine, likewise guarana of which caffeine is the active principle, were never of any use to her. Cannabis indica is perfectly negative and the patient is so annoyingly familiar with every other known remedy for headache and the inefficacy of all of these, that in her paroxysms of pain you will not wonder, notwithstanding I have a strong prejudice against the drug, that I have occasionally resorted to morphia, which of course, relieves the pain, yet is invariably followed by severe vomiting. I did not try antifebrin because by this time I had lost faith in remedies of that sort for this patient.

When she came out of this storm I found that the former effectual treatment by cardiac tonics and alkalies had utterly lost its power. This fact together with absence of relief from medicines which benefit other forms of headache, still farther convinced me that gout and not neuralgia was the root of the ailment and I finally resorted to absolutely anti-arthritic treatment — wine of colchicum and iodide of potassium — the diet being carefully regulated. That I did not do so before, in view of my diagnosis, was due to my hope that the cardiac tonic and alkalies would prove effectual, as indeed they decidedly did for six months. Almost at once after beginning to take the remedies for gout the patient experienced a heretofore unknown sense of relief. Time is needed to prove that she has been wholly relieved of her suffering, but she is already in a condition of comfort to which she has long been a stranger, and although at times she is conscious of pain, it is so mild in character she does not consider it of moment and I hope it is due to nothing more than nerve-memory. Twice weekly, I give her a strong secondary galvanic current. This is acting well as a nerve tonic and the

patient is more vigorous in every sense. She is taking eighteen drops of the wine of colchicum root and eight grains of the potash, three times daily.[5]

A prominent feature in the symptoms of this case has been the weak heart; careful stimulation of which contributed largely to the well-being of my patient, during the six months of almost entire freedom from severe pain.

This point merits especial mention. I believe we neglect the heart in many cases in which if this organ were stimulated, patients would sooner reach a condition of comfort. In the patient in question, notwithstanding she has been a victim of pain for thirty years during which she has received such a variety of treatment, that it is difficult to name a remedy with which she is not familiar, and in spite of having passed through the hands of very many physicians, her heart has never before been carefully examined nor directly treated.

The heart being the active agent in the general circulation, distant localities suffer when this organ becomes feeble, in the same sense as would the outlying beds of a garden, the source of whose supply of water we may suppose to be a centrally located pump, if the pump lost power and became unable to give the distant beds their needed supply. In short, the necessity of aiding the heart in every case of chronic headache, is the one point which I would especially emphasize, particularly because I find it universally neglected in the books. Indeed, there are few ailments of any nature, in treating which it would be unwise to aid the heart. But, it is, I believe, too apt to be the case, if the physician find a regular cardiac beat and no murmur, that he pronounces, or deems, the organ in a normal condition, when there may be a lack of cardiac energy as shown by the radial pulse and by the existing relation of the heart-sounds to each other.

It is but recently that I treated a case of chronic hyperæmia and catarrh of the pharynx, with distended veins and hypertrophy of the follicles, in which case I also found a weak heart and a gentle systolic murmur. Until I resorted to cardiac stimulation I made but slow progress in relieving the catarrhal ailment, which, however, decreased rapidly so soon as I began to aid the heart, the condition of which undoubtedly had much to do with the pharyngitis. This suggests a second case of headache of long duration in which the pain was located strictly over the occiput. The anti-neuralgic gamut of remedies, the patient told me, had been used in vain. He was frequently unfitted for his work which was wholly intellectual. His sleep had long been irregular and insufficient. His moods became despondent. He was never free from pain, which, however, varied in degree. This is the brief history of many years.

I found cold hands, injected conjunctivæ, a muddy skin. Examining the heart, though it was free from murmur and pulsated with regularity, its tones and impulse were not sufficiently strong for a well-developed man, and the first sound was decidedly weaker than the second. I at once prescribed the tincture of strophanthus four times daily, the fourth dose being larger than the other three and to be taken at bedtime. Very soon the chronic occipital pain was relieved and up to this time the remedy has been efficient. According to various writers occipital headache is not understood. Nevertheless, it seems to me when cause and effect are as clearly shown and as easily relieved as in the case I have just cited, that we do get some idea of the conditions whose united result is headache. Still, even here, why the pain should confine itself strictly to the occiput, is, I must admit, a *quid ignotum*. I have, however, sometimes questioned whether the sudden and almost right-angled curves in the vertebral arteries just before they unite to form the basilar artery, are not a factor in occipital pain when the heart is weak or tired. At any rate the pain is almost wholly in the zone of these four abrupt turns in the two vertebral arteries.

Could it be vaso-motor pain due to pressure caused in these arteries by the resistance offered to the circulation by the arterial curves, plus the local accumulation of blood due to the weakened *vis a tergo* resulting from a feeble heart? There is much to learn here and I advance these theories with great diffidence. Erb[6] says: "In regard to the etiology of this form of headache but little is known;" and I have at present a case under treatment which is very puzzling.

The patient dates his neuralgia as far back as his student days when he worked incessantly and neglected general care of his health. His daily life is spent in severe brain work. He passes at least eight hours daily in a chemical laboratory, which might lead one to suppose gases and odors to be one element in his headache from which he says he has not once been free for sixteen years. But, inasmuch, as during the long vacation, which is lived largely in the open air in a very high locality, the pain continues without intermittence, the natural inference is that laboratory work has little or no influence in the causation of it. Moreover, the headaches began years before the patient became a chemist.

This seems one of those cases in which, as Erb says, no anatomical cause of pain can be shown to exist, and thus far it has defeated me. It need not be said that medicines, electricity, regimen, gymnastics, etc., have been vainly tried. Cannabis indica, antipyrine, antifebrin, galvanism have no effect whatever. I found that friction over the occiput and upper portion of the nape of the neck afforded decided relief. The patient continued the procedure but finally thought that so much movement increased the pain and it was abandoned.

He cannot sleep upon the back without causing intense exacerbation of the pain, and is obliged to use an extremely thin pillow, for, when lying upon his side the slightest bend of the neck aggravates the pain. The increase of pain in the dorsal decubitus and by a bend in the neck is the possible result of retarding the circulation. Temporary relief from friction was the probable consequence of lessening the pressure in subjacent bloodvessels. These are points which seem to support my theory in relation to the outcome of the sudden slowing of the blood-current by the curves in the vertebral arteries.

Cardiac tonics have as yet produced no result, but have not been used long enough to prove their lack of benefit.

Blisters so highly recommended by Anstie and others, have not been tried, because the patient said he preferred the disease. The cannabis indica cure of this form of headache, so vaunted by Stephen Mac-

[5] Four weeks later: The slight pain which persisted after the beginning of the anti-arthritic treatment has now disappeared.

[6] Ziemssen's Cyclop. Vol. XI.

kenzie in *Braithwaite's Retrospect* for July last, and before him by Anstie, Reynolds and other writers, has been pushed to intoxicating doses, and, excepting exhilaration, without apparent effect of any nature. This is the most obstinate case of headache in all my experience. During his youth the patient was favored with intervals of relief; but, let me recall his statement, that for *sixteen* years there has not been a single intermission in the pain which, in short, has now been so long a habit with him that he is quite able to be natural and normal in manner and daily life. He has an irritable and therefore a sensitive heart, otherwise his general functions are undisturbed. His appetite is always good, but he has a look of chronic fatigue.

One thing that should not be forgotten is, that he is a smoker, but smokes moderately. I found that early in the day he was very dependent upon his tobacco, so much so that unless he had previously smoked, he could not deliver a morning lecture without dizziness. For that reason I requested him to delay his first smoke by half-hours until it became noon. The patient, meanwhile, being obliged to fight a battle in which he finally conquered, to his benefit. I cannot believe this a tobacco headache, for it began long before the patient smoked at all, and used to be more intense than it now is. The patient's eyes have been often and carefully examined by able occulists, and every defect corrected by the proper glasses.

He is not in any sense a hypochondriac, and I believe the case to be perfectly honest, so much so, indeed, as to give me the uncomfortable suspicion that this headache is my master — thus far at any rate. It can, however, be said that the pain although persistent, seems to be wearing away, for it is less intense than it formerly was.

One important feature in this case should be mentioned: I have quite recently been led to surmise that mental worry has been an influence in this prolonged headache, for it has become apparent that a decrease in the intensity of the pain has coincided with a gradually increasing relief from the cause of the worry.

The cases I have chosen in illustration of my subject do not seem to belong to the class of merely peripheral neuralgias, and for that reason are the more baffling.

I should have been glad to have quoted largely from writers on nervous affections, but, so far as my experience goes, in the domain of inveterate headache the books are well-nigh useless. I hope, however, to learn something from those who speak on my paper. Something more useful, at all events, than Strümpel's[7] final remark on headaches which defy every remedy.

He calmly says: "Still the patient has the comfort of knowing that after years and decades, the affection, when old age is reached, not rarely ceases of itself."

A CASE OF ATHETOSIS.[1]

BY C. P. PENGRA, M.D., BOSTON.

ATHETOSIS is the name of a disease that was first recognized and named by Dr. W. A. Hammond, of New York, in 1871. It is characterized by an inability to retain the fingers and toes in any position in which they are placed, and by continual motion.

Since his first paper in 1871, there have been thirty-eight cases reported from Europe and eight from the United States; and it is this rarity of its occurrence that has induced me to present this case to the Society, with the hope that it may aid in clearing up the obscurity that surrounds its etiology, pathology, treatment and claims as a definite disease.

In all of his writings Dr. W. A. Hammond claims that athetosis is a distinct disease, and, while admitting its analogy to chorea and cerebro-spinal sclerosis, does maintain that it is independent, and can be so diagnosed. In this he is supported by Dreidenberg, in "Vratch," who goes even further, admitting that it is not necessarily a result of hemiplegia, but may even be idiopathic.

Opposed to this view are Putzel,[2] Sturges,[3] Leube,[4] G. A. Hammond and Birdsall,[5] and others.

In all cases reported, there has been noted, at some previous period, a history of epilepsy, chorea, hemiplegia, or other cerebral disturbance; while the case of Leube, after having had athetoid movements for four years, actually developed into, and continued as, ordinary severe chorea. The history of the present case is no exception to the rule; and, considering the lesions most often found in post-mortem examinations, it seems that we are forced to believe that athetosis is too intimately allied to chorea, hemichorea, and the like, to merit its claim of being distinct. The lesions found are in the corpus striatum, optic thalmus, or both, and the cortex cerebri, and are the same as occur in the allied troubles. My diagnosis depends upon the facts, that, in this case, the spasms are limited to the right hand only; that they are uniform, slow and quiet; that the muscles contract or extend together, and are firm and tense; that there is no trembling in any position of the hand or body; that the muscles of that arm are well developed; and that there is no scanning in speech. Hysteria is eliminated by the age at which it began and by the present condition of the patient, Mrs. Anna B. Grover, age twenty-two, born in Marshalltown, Pa. Her family history is very good, excepting slight rheumatic attacks in the father's later life, and paralysis agitans in one aunt.

Her own health has been exceptionally good, with the following exceptions received from her father: —

"Anna was healthy, and perfect as could be until about two and one-half years of age, when a servant girl caught her by the arm, and tried to pull her up stairs. A physician was called, and pronounced it a bad sprain. After the usual bandaging, and carrying in a sling for two weeks, it seemed as well as ever. About three months afterwards, having eaten heartily of green Lima beans, pods, etc., in the garden, she was taken at night with violent spasms, purging and vomiting, followed by great prostration, emaciation, unconsciousness, and paralysis of said arm, and also of speech, that continued for three months. During this sickness she was almost continually in motion, even after getting up. Her voice was entirely gone, and the arm now affected was useless. Many different doctors and treatments were employed. The voice gradually returned, and the arm improved. At first the hand was strongly contracted and painful. The arm was carried behind her back, through shame, till about the thirteenth year, which produced a lateral

[7] Specielle Path. u. Therapie.

curvature, for which a brace was worn eighteen months. All improvement has been from the shoulder towards the hand. Electricity seems to have done the most good."

Present Condition. — Her general health is of the best, since the foregoing. "The hand," as she calls it, is not at all painful: there is no movement at night, or unless her attention is called to it, or she is excited. A decided effort of the will has only the slightest effect upon its movements. At times it contracts powerfully enough to tear a glove: to open it, she must use her left hand, and forcibly extend the fingers to their utmost. When left alone, the contracted fingers will return to normal in from two to five minutes.

In most of the reported cases the movements have been most marked in the thumb and little finger. In her case the thumb and first finger are most affected. The first finger is often forcibly extended, while the others are as strongly contracted. The hand is of little use, as there is no telling when it will take hold or let go. At present she is under no treatment, and is impressed that it is slowly improving.

In all cases the most improvement has been from electricity; and, contrary to theory, the faradic current has proved the more useful. No cure has been reported; and, while the trouble is regarded as incurable, it has never been known to prove fatal.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.[1]

ALBERT N. BLODGETT, M.D., SECRETARY.

DR. C. P. PENGRA presented

A CASE OF ATHETOSIS.[2]

DR. J. J. PUTNAM asked: Are the reflexes of the lower extremity altered?

DR. PENGRA: Not at all. There seems to have been no trouble with any part of the body except the arm and the vocal organs. The lima beans were regarded as a poison by her parents, but from her history she undoubtedly had an attack of gastro-enteritis.

DR. PUTNAM: Are the muscles of the right arm hypertrophied?

DR. PENGRA: There is no enlargement that I know. The muscles seem stronger. They are set and tense.

DR. HAMILTON OSGOOD: What is the condition of the hand in the night?

DR. PENGRA: Quiet. She has never had a contraction in the night. There was a time, a considerable time ago, when she had slight contractions, I believe, but at no time has she had contractions since she has known anything about it.

DR. PUTNAM: I would like to say only a few words about the case; it is an interesting one. I suppose that it is very difficult, almost impossible, to draw any sharp dividing line between these disorders of movement. Dr. Gowers wrote, so far as I know, the most satisfactory paper on the subject a few years ago, and showed how one could trace gradual degrees of difference in these cases through the whole scale from the typical athetosis even, he thought, as far as the late rigidity of hemiplegia; but without going so far as that, it seems very certain that there is only a sliding scale between the typical cases of athetosis and what has been known under the name of post-hemiplegic chorea; the difference consisting partly in the character of the movements, and partly in the fact of the greater or less amount of paralysis associated with them.

I was rather surprised to hear the Doctor say that so few cases have been reported, for I should not say that it is very rare to find cases that are as typical as this case. I would not speak of this as an absolutely typical case, because, as a rule, the movements would not stop in the typical cases when the patient was holding the arm at rest with the hand supported with the other hand, as at present; and then the movements are usually much more varied in character, involving extension quite as much as flexion so that the fingers are thrown about in a worm-like action all the time, while here the flexion predominates, and the flexor spasm is certainly much more marked, I should say, than in typical cases of this disease. However, I do not see how it can come in any other catagory than that of one of the involuntary disorders of motion of that type.

DR. PENGRA: In regard to the number of cases, I referred merely to the number of cases recorded. I have no doubt that there are plenty of cases, as we are quite aware, in most any line of disease, that, while not being recorded, have existed. We must realize that only in 1871 the disease was recognized as such. From the literature that I can read — of course my experience has not been sufficient to warrant my statement — but, from what I can read I am inclined to think that athetosis is an organic disease. I think I so stated in my paper. The disease I do not think I stated as a typical one, from the peculiarity of the motion.

The definition that Hammond gives is "a disease characterized by an inability to control the fingers or toes, and a continual motion." And in his reports of the cases, and he is the father of the disease, you might say, so far as the diagnosis is concerned — in the reports of his own cases there has been such a marked remission that almost the first thing that I thought of in connection with the definition, was the superfluousness of the word, "continual." During the greater part of the time that my patient was suffering from the trouble, and the paralysis, which seemed to have been the precursor of the disease, she was in constant motion that included a large portion of the body, I believe mostly on the right side, but the paralysis was limited to the right arm. The motions of the arm did include movements toward the back to such an extent that she finally put it on the back and left it there.

I do not think I referred to the case as being exactly typical; so far as I can see there is no typical athetosis.

My statement suggested as strongly as I could state from my knowledge of the cases, that it is an organic cerebral disease. The statement of Dreidenberg is the one statement that counteracts all others so far as it goes, to the effect that it may be idiopathic, but his own case does not sustain that, inasmuch as one of his cases were preceded by hydrocephalus and another case by epilepsy; and as to the

[1] Concluded from page 63.
[2] See page 80 of the Journal.

matter of the word "continued," it is certainly not right, because there have been no cases recorded where remissions have not occurred.

DR. C. F. FOLSOM: It seems to me, Mr. Chairman, that it is a very interesting case, and that we want to understand in regard to a good many points what we cannot make out to-night, before calling it clearly a case of athetosis. If it is athetosis it differs in a great many essential respects from what is called typical athetosis. It is a question, of course, how far movement of this sort can be considered as belonging to that group, and due to organic trouble. There doesn't seem to me any marked hypertrophy of the hand, and the movements seem very different from the movements of athetosis; the flexor muscles contract almost instantly, as soon as the resistance is taken away. It is quite possible that there may be a little difference in the knee-jerks. The whole group of cases is certainly a very interesting one. I suppose that nobody is satisfied in his own mind just what to call athetosis, and what not, but the fact of the hand being quiet during sleep, and perfectly quiet so long in the position that the patient has it now, seems to me to make it very unlike what is described as athetosis.

DR. PENGRA: Would the Doctor suggest some name for it?

DR. FOLSOM: As I say, I would not wish to express an opinion without having it under obervation some time. It reminds me of a case that was in Dr. George B. Shattuck's ward in the City Hospital, which suggested athetosis. Strangely enough a case of real athetosis was in the ward at the same time. The former had these features of being quiescent during sleep with no hypertrophy of the muscles, and the contractions of the muscles were sudden and violent and quick, instead of slow and gradual, and there was the feature of quietude for a long time. It was finally thought to be a functional trouble, and in the course of time, by rest and cod-liver oil and tonic treatment, it almost entirely disappeared. It seems to me it is a difficult matter, sometimes, to make a diagnosis between the various forms of anomalous chorea and hysteria and athetosis.

DR. PENGRA: I would say that according to the best authorities that I can find on the subject of diagnosis — that is, in print — this is the essential feature, which I quote from Dreidenburg, "that there is no trembling in any position of the hand or body, that the muscles of the arm are well developed, and there is no scanning in speech; that the movements are uniform and slow and quiet, that the muscles contract and extend together, and are firm and tense."

DR. FOLSOM: He evidently has in mind, I think, disseminated sclerosis, in his diagnosis; in regard to the scanning of speech, etc.

DR. PENGRA: I don't pretend to be an authority on the subject at all. I brought it before the Society to hear some opinions beside my own. Experience, of course, would be a teacher that a young man could not get from books. In regard to the treatment of the true athetosis, there was one writer, in fact this same Dreidenburg, who stretched the median nerve, but he finally had one case where he stretched the nerve and the nerve remained stretched, and as in no previous case he got any result that lasted more than eight days, he finally gave that up, and resorted to electricity entirely.

DR. HAMILTON OSGOOD read a paper on

INVETERATE HEADACHE.

DR. WHITTIER: I heartily concur in all that Dr. Osgood has said with reference to the difficulty of dealing with the subject of inveterate headaches,— that it is quite as difficult as dealing with the disease itself. A difficulty which we all appreciate, with which all have had an experience more or less aggravating. The general practioner, into whose care most cases of this disease come, early and late in life, generally concludes, from his reading and from his personal experience that but little can be done other than by palliative measures; that entered upon in puberty, the disease pursues in the great majority of cases a course more or less paroxysmal, of varying degrees in intensity and of frequency, until the grand climacteric; by which I wish to be understood as intimating that the disease is, by the influence of sex, in the proportion of five females to one male, and that the causative influence of sex, age, heredition and temperament, exceed all other predisposing, in fact all other causes combined.

The difficulty of dealing with the subject of inveterate headache, so far as the literature of the subject is concerned, seems to me to be two-fold; first, in the diffusive character of the articles written by men in general practice, and secondly, in the technical character of the contributions made by neurologists.

Hughlings-Jackson, writes of a discharging lesion of the cerebral cortex in the sensory area. Elsewhere I find that the causative influence of headache is divided into two parts, "hemicrania-sympaticotonica and hemicrania angio-paralytica," rather discouraging terms to the average student of general medicine, for whose instruction I may venture to assume that such writings were intended. We must, however, admit that a great advance has been made in the desirable direction of definition and of eliminating uncertain and undemonstrated causes of this most formidable malady.

Having had the customary and somewhat extended notification of an invitation to speak on this subject this evening, I quickly came to a realizing sense of the difficulties of the subject, and found it needful to apply to the subject the method which for many years I have applied, with results generally very satisfactory to myself, in examining any difficult subject; namely, a method of analysis and tabulation. I, therefore, have the pleasure of submitting for your examination,

A SYNOPTICAL TABULAR VIEW

arranged and grouped according to a system which has always been of the greatest assistance to me in fixing the essential elements of difficult subjects.

I offer this as my contribution to the topic under discussion.

Dr. E. G. CUTLER said: I was much interested, Mr. President, in the first case that Dr. Osgood read. After he spoke to me about the case, in looking for some cases I found that I had nothing of my own, but I found in the library, in the last report of St. Bartholomew's Hospital a collection of fourteen cases not unlike those of Dr. Osgood. It is a paper written subsequent to another published several years ago, of cases in which was found a large increase in the uric acid in the urine, the chief symptom being that of headache. The history of these cases always showed

HEADACHE — A SYNOPTICAL VIEW.

Locality Division (Dr. Hughlings-Jackson)

- Frontal headache (abdominal disorders)
- Vertical headache (cerebral disorders)
- Occipital headache (circulatory disorders)

Pathology of "Inveterate" Headache.

- Congestion
  - Active
  - Passive
- Cardiac hypertrophy
- Vaso-motor disturbances
- Abnormal conditions of blood
  - Hydræmia
  - Defective arterialization
  - Defective excretion
- Meningitis
- Cerebritis
- Abscess
- Tumors
- Softening
- General plethora, or anæmia
- Cardiac or pulmonary diseases
- Affections of
  - Stomach
  - Liver
  - Intestines
- Renal and cutaneous diseases
- Fevers and acute inflammations
- Ague and chronic malarial poisoning
- Gout and rheumatism
- Uterine disorders
- Hysteria
- Neurasthenia
- Syphilis

For Practical Purposes the Etiological Order may stand as follows: —

- **Structural Headache (intra-cranial disease)**
  - Meningitis
  - Cerebritis
  - Abscess
  - Tumors
  - Cerebral hemorrhage
  - General paralysis of the insane
- **Congestive**
  - Active hyperæmia
    - Hypertrophy left ventricle
    - General plethora
    - Mental and emotional disturbances
    - Catamenial irregularities
  - Passive hyperæmia
    - Dyspnœa
      - Cardiac
      - Renal
      - Pulmonary
    - Hepatic, intestinal or peripheral
    - General anæmia
- **Toxæmic**
  - Altered conditions of blood
    - Renal disease
    - Inflammations
  - Alcohol, opium, carbonic oxide, lead, etc.
    - Defective arterialization
  - Syphilis (periostitis, etc.)
  - Chronic malarial poisoning
- **Nervous or sick headache**
  - Megrim
    - Migraine
    - Hemicrania
    - Predisposing causes
      - Sex, age
      - Hereditary tendencies
      - Nervous temperament
      - Deficient tone
      - Anæmia
      - Errors of refraction
    - Exciting causes
      - Exhaustion
        - Physical
        - Mental
      - Psychical disturbances
      - Impure air
      - Bad hygiene
      - Sexual excesses

the existence of gout or some such affection in some member of the family, and the headache usually was periodical, either lasting for a long time, or coming on at irregular intervals, perhaps of hours or days or weeks or months, and lasting for years.

The treatment which was found most successful, I believe, was that of a diet in which there was a great diminution in the nitrogenous matter, a diet largely liquid-farinacious; and also the treatment by hydrochloric acid. It was found by experiments which have apparently not been disproved, that under the treatment with hydrochloric acid the amount of uric acid diminished, and with alkalies it increased, and it was found that at the same time this symptom of headache would be done away with more effectually than by any other means. This article is a very interesting one, and I have not seen that it has been contradicted.

Also, an interesting point in this first case that Dr. Osgood spoke of, was the matter of the tooth. I not do remember whether he said that it was a molar tooth that was affected. In looking over the literature of the subject I think it is claimed that those headaches which depend on the teeth are apt to be in the back part of the head; I think, in his "Disorders of Nutrition and Digestion," Lauder Brunton speaks of several cases where caries of the molar teeth either in the upper jaw or lower jaw was accompanied by a headache in a certain region. I think in the upper jaw he claims that the temporal region and the occipital region are the two seats of the pain, and the first thing that he does, when a man has a headache there, is to examine his teeth, or to send him to the dentist.

This regional method of diagnosis in headache and the treatment that is laid down for it I have had little experience in, so that I cannot judge as to how good it is. In my practice I have had very little of the sort. It is only in the Hospital and Dispensary that I have seen very much of the kind, and it is rather difficult to locate the headache there, I find, because you cannot always get the patients to locate it in the same place. I have, however, seen headaches which depended upon some disease of the teeth, which having been relieved, would subsequently disappear; or where there was tenderness which would be localized in the region of the trifacial, where it has seemed to me that gelsemium has worked well. I have also seen cases where some trouble in the nose was apparently the cause of it, and when they have been sent to the throat-room in the Hospital the pain has disappeared without further treatment. I remember also a case of frontal headache, such as Lauder Brunton says is relieved by acids; at first it seemed to illustrate that, but subsequent examination seemed to show that it was not so.

Dr PUTNAM: Dr Osgood's paper calls to one's mind a large number of very interesting points, and of course it would be impossible to do anything like discuss them all. That there is such a thing as gouty headache in the sense that the word "gouty" is commonly used in this country, as indicating in the most general way a disorder of the assimilation and nutrition, I suppose there can be little doubt. That is to say, that this is one of the many neurotic symptoms which are met with under these circumstances in what is called lithæmia, which is the nearest approach to gout which we have except in special cases. I think it is difficult however, to determine that the lithæmic condition acts as a cause of the nervous symptoms. In the regard to the relation of the heart to headache, I suppose that we might do a good deal more than many of us do in the therapeutics of general diseases by stimulating the heart; although I think it is very hard to say many times whether the heart-sounds are a little weak or not, and that unless one examines with great care and many times, and both before and after treatment, it would be very easy to attribute to the cardiac remedy a result which really belonged to something else.

So far as the occipital headaches are concerned, I feel pretty sure with regard to some varieties of them, that they do not arise from the heart. I have seen a large number of these headaches, as every one must have who has to do with nervous diseases, because they seem to be extremely common, in connection, largely, with over-work, in persons otherwise in good health. I have, indeed, under my care at present, a lady who suffers greatly from this headache, which continues in spite of an improvement in her general health, and she has heart disease. On the other hand, I have treated for a long time a gentleman who prides himself on his vigor and his muscle, and he has had this headache for a very long time also, though not in a severe form; but in his case it has disappeared, apparently without any one being able to say why. At one time he thought that massage helped him, and at another time electricity. He has never presented any signs of weakness of the heart. Of course, I do not mean to imply that Dr. Osgood claims that all cases are due to that cause.

Another cause of occipital headache which should be borne in mind, is one which Dr. Seguin called attention to some time ago, and that is uræmia. I have recently had a patient, a lady with chronic Bright's disease, in whose case this sympton has been present. In regard to the flushing of the ears as occurring in these headaches, as a sign of cardiac disease, I must say that I cannot agree with Dr. Osgood. I think it is well known that flushing or paleness of ears or face is a very common one in migraine. Writers have been divided as to how much influence is to be attributed to alterations in the vascular supply of sensitive membranes as a cause of the pain, or whether the pain may be due to spasm or dilatation of the vessel itself; and for my part I am of the opinion that it is only a concomitant symptom as a rule; it is common to see cases of typical migraine without any such apparent changes and again, vascular changes occur so often in other neuralgias, that it seems to me on the whole that the fairest way of looking at it is as a concomitant symptom, and not as a rule, a cause of the pain.

And that leads me to say that the patient whom Dr. Osgood first spoke of, is one whose case I have known of for a number of years. I have cross-questioned her with great care in regard to the congestion of the ears, and she has assured me that although the flushing of the ears is almost always associated with the headache, the two conditions are not entirely parallel, and that occasionally, sometimes in the course of a long headache the pain may be on one side, and the flushing on the other. As regards the gouty tendency of this patient, it is a very interesting question, and I did my best, as I thought at the time, to treat her from that point of view, a year ago.

It is an interesting and important matter, and I am glad Dr. Osgood brought it up.

I advised her to give up sugar and starch. She did that, and got better. She took, also iodide of potash, and lithia for a considerable time. Then, after a time that diet failed, and we tried an opposite course, giving up the meat, and confining herself to a non-nitrogenous diet, and for a time that also worked very well, so that I became quite convinced, especially as I had seen something similar in another patient with migraine, about the same time, that it was the change in treatment, and not the specific diet that had produced the effect.

In a large number of these cases almost any change of the conditions under which the patient is living will be of service, and I will say in regard to this patient, that she was very free from headache at one time, as a result of a visit to another climate, but a second visit to the same place did no good.

Dr Myles Standish: I want to refer to the headaches caused by errors of refraction, as we have heard very little about them here this evening. A very large proportion of the headaches in young children, children going to school, are due to errors of refraction, and are cured by correction of that error. In older persons very often error of refraction is the cause. I have seen very striking, almost marvellous cases. I remember one young lady who had been an invalid for a number of years, never going out on account of her constant headache; a pair of glasses enabled her to go where she pleased, to go to picture-galleries, and a year later she came back, and said she had never had a headache since. It is not a single case, but we see it very often. I see many such cases every year. I perhaps have had this thing forced upon me from my own experience in the matter. From my boyhood I have had very severe headaches every two or three weeks. When I came to the medical school I took everything that I could find in the form of drug, without any result whatever; but correction of my error of refraction has reduced my headaches. I still have them occasionally, perhaps once in two or three months, where as formerly I had them every two or three weeks; and I have gone a year with only one or two headaches. When a headache lasts all the time, of course it is not so likely to be due to error of refraction as to some other cause, but when it follows close application of the eyes, especially near work, I think error of refraction should always be ruled out before going any further.

Dr. Putnam: I simply want to say that I most sincerely agree with what Dr. Standish has said, and I did not speak of it because I did not think of it at the moment, and this lady had been to Dr. Wadsworth to have the refraction tested.

Dr. Folsom: I wish to speak of a case in connection with Dr. Putnam's allusion to the analogy between these cases and epilepsy. Of course, a sensory discharge may take the place of a motor discharge. I was reminded of a patient who was a type of health in every other respect, who had a very persistent headache for a number of years. She had her eyes examined for astigmatism by a number of ophthalmic surgeons and almost every remedy tried, until it occurred to me that it might be similar to epilepsy in type. The continuous use of bromide, as it is used in epilepsy, relieved her entirely. I wish that Dr. Standish would speak of the difficulty of detecting this astigmatism, and the very minute amount, requiring most careful examination, which may cause headache, an amount that would be overlooked by the ordinary examination. It seems to me it is a matter which physicians in general practice should know, and it is a point which has embarrassed me a number of times. As an interesting point in regard to that, a person may have considerable amount of astigmatism, and yet have no headache except under certain physiological conditions. That is to say, if in perfect health he has no headache at all; he can read and write, and do it late at night; but as soon as he begins to run down, a very moderate amount of reading and writing will cause headaches. I have one patient who, when he finds that he needs glasses, goes on a vacation.

Dr. Standish: It seems to me very rational that when the man's condition gets run down, his ciliary muscle, which is very delicate, might be affected.

Dr. Knapp: I agree with Dr. Standish on the importance and dangers of refractive headaches. In every case of severe persistent headache that I see I try to get a thorough examination of the eyes for any error of refraction. I may say that it is about the only form of reflex headache that I have been led to take very seriously. I have looked for the other forms of headache which are said to be due to displaced uteri, cerumen, and this, that and the other, and as a rule I have not been able to find them. But I do find them in errors of refraction.

Dr. Osgood said he did not understand the rationale of the hydrochloric acid treatment of a uric acid condition, and the proof that alkalies were beneficial in that condition was that his patient steadily improved under the use of them.

In reply to Dr. Putnam, he said that the color of the ear in this case could not be merely a "concomitant" for, that it held a direct relation with the state of the heart, was shown by the fact that during attacks of pain the ear became less and less livid in strict coincidence with an actual increase of power in the first sound of the heart. Dr. Putnam virtually admits that in his cases of occipital headache, fatigue or debility always coexisted. Inasmuch, then, as the heart never rests, is always at work, and has less repose even than the lungs, it must partake of the general debility or fatigue of the body, and consequently has less than its normal power to send the blood through such sudden arterial curves as exist in the vertebral arteries.

In regard to the eyes of the patients he had cited, Dr. Osgood said that in his paper he had remarked that all possible care was given to the eyes of one of them. He had also made himself certain that everything had already been done to assure the proper condition of the eyes of the other two patients. He thought there would be no disagreement in relation to his assertion that inveterate headache was one of the most troublesome and discouraging ailments with which the physican has to deal.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-First Annual Meeting, held at Pequot House, New London, Conn., July 17, 1888.

MORNING SESSION.

The Society was called to order by the President, Dr. J. S. Prout, Brooklyn, who alluded in his opening address to that loss sustained by the Society in the

death of Dr. C. R. Agnew of New York, and suggested that action be taken. On motion, Dr. Gorham Bacon and Dr. W. H. Carmalt were appointed to prepare an appropriate minute on the subject.

Drs. Green, Theobald and Carmalt were appointed as the Business Committee.

DR. E. WILLIAMS, of Cincinnati, on account of failing health, presented his resignation. This was accepted and on motion of Dr. Carmalt the by-laws were suspended, and Dr. E. Williams were elected an honorary member of the Society.

DR. W. H. CARMALT presented the report of the Committee of Conference on the Congress of American Physicians and Surgeons. The report was accepted, and it was decided that when the Society adjourns, it adjourns to meet at the Arlington Hotel, Washington, D. C., September 18th, 1888, at 11 A.M.

On motion of DR. GREEN, it was decided that the meeting should be strictly for scientific matters, and should not be regarded as a business meeting; that is, should not take the place of the annual meeting.

The reading of papers was then taken up.

Two papers by DR. S. SEXTON, of New York, entitled

PERIOSTITIS EXTERNA OF THE MASTOID,

and

SOME OF THE INDICATIONS FOR EXCISION OF THE DRUM-HEAD AND MALLEUS,

were read by title.

A CASE OF AURAL VERTIGO (MENIERE'S DISEASE), RELIEVED BY EXCISION OF THE MEMBRANE TYMPANI AND MALLEUS.

by DR. C. H. BURNETT of Philadelphia,

The patient was a young, unmarried woman, thirty-seven years of age, who six years previously had been under treatment for chronic naso-pharyngeal catarrh, and chronic catarrh of the left middle ear, accompanied with hardness of hearing, tinnitus aurium, and a sense of fulness in the affected organ. Treatment of the catarrhal disease of the ear produced no benefit. After the lapse of six years, the symptoms already named grew worse, and there was superadded marked aural vertigo. The membrana tympani in the line of the malleus handle was found adherent to the promontory, and the consequent retraction of the entire chain of bones was held to be the cause of the aural vertigo and the sense of fulness and of the tinnitus.

The operation of excision of the membrana tympani and the malleus was performed under ether, May 21st last, with entire and immediate relief to the aural vertigo (which before had often been sufficient to cause the patient to hold to a lamp-post for support) and to the sense of pressure and tinnitus, which good result has been maintained to the present time. The hearing was practically unaffected by the operation. The incus was detached from the stapes but could not be removed as it slipped into the attic and grappling for it is not advisible on account of the risk of irritation. Its removal, furthermore, would have no effect in the result of the operation.

DISCUSSION.

DR. J. O. TANSLEY, New York. I have now under my observation a girl on whom this operation was performed some eighteen months ago. When she came to me the whole internal canal was filled with polypi and she presented serious brain symptoms. I took out all the polypi and found a portion of the drum remaining and above a localized necrosis into which a probe passed at least one-fourth of an inch. The patient has been under observation every day for two months, the local necrosis is healed and she is doing well. There are still some brain symptoms. It seems to me that this is a very serious operation and I should hesitate sometime before performing it on account of the results that might occur. In this case the result seems directly traceable to the operation.

DR. C. H. BURNETT, Philadelphia. My patient did not remain in Philadelphia but I was informed that two or three weeks after I saw her a discharge appeared. I think that there is still a slight discharge but the membrane is forming. In another case, a slight discharge appeared soon after the operation but ceased after the membrane had re-formed. The case reported by the last speaker was not one of the class to which I have alluded. The operation was evidently not properly performed if there remained a portion of the membrane and there was necrosis. I have not found this a dangerous operation. No one has reported bad results from this operation properly performed.

DR. CHAS. J. KIPP, Newark. This operation has been performed a number of times by a foreign operator for the relief of tinnitus and vertigo, but he has given it up because it did not relieve these symptoms satisfactorily. He, however, did not have any bad results.

DR. S. SEXTON, New York. I have performed this operation between fifty and one hundred times in the past few years, and have obtained decided benefit in a number of cases of tinnitus and other subjective symptoms. I have known of no case in which there was aggravation. In many cases where there has been no marked tinnitus the distressing sense of pressure has been overcome. The tinnitus is not always relieved by the operation.

DR. BURNETT has referred to the closure of the drum-head. My principal endeavor has been to avoid re-formation of the drum-membrane. In a number of cases where this occurs the good hearing is lost. I have prevented this by the application of a solution of salicylic acid in ether to the margin of the closing membrane. This has succeeded even where the membrane has closed down to a minute opening. In regard to the purulent cases to which allusion has been made, I have operated on a number, and on the whole they are the more satisfactory cases.

DR. B. ALEX. RANDALL, Philadelphia, was invited to take part in the discussion of the Society. He said: It may be that in Dr. Tansley's case the operation was done for the necrosis. The presence of polypi of the size referred indicates too great neglect, and the results are more probably attributable to this neglect than to the operation.

DR. SEXTON, New York, then exhibited a new portable battery for the storage of electro-motor force, and a new head-lantern for the employment of electric light in surgery.

The battery was made at his suggestion by the River & Rail Electric Light Co., of New York. It consists of three cells, and will light a six-candle electric light. The lantern is a modification of that of Trouve, but much lighter, and having a non-conducting base. Such a light is almost necessary in operations on the

ear where ether is used as an anæsthetic. The battery will work continuously for twenty-four hours, and will retain its power for several weeks or months. It may be charged by a dynamo or by twelve gravity cells. When not in use, the storage battery may be kept in connection with the gravity cells.

REFLEX INFLUENCES IN THE PRODUCTION OF NASO-PHARYNGEAL CATARRH,

by Dr. A. H. Buck, New York.

The object of the paper was to call attention to those comparatively remote exciting causes of naso-pharngeal catarrh, which act, so far as it is possible to explain their mechanism, through the intervention of the vaso-motor fibres of the sympathetic nerve. We know little of the direct exciting causes of naso-pharyngeal catarrh. The most common indirect cause is chilling of the surface of the body. According to certain authorities, affections of the teeth should rank next in order of frequency. The author had, however, seen very few cases in which dental disturbances played the part of a promoter of naso-pharyngeal catarrh, or of aural disturbances. Some of those indirect causes which he had observed were then enumerated. Irritation of the gastro-intestinal canal is, in not a few instances, a strong exciting cause of naso-pharyngeal catarrh and of all the aural disturbances growing out of such a catarrh. A male, forty-five years of age, had for years been more or less a sufferer from naso-pharyngeal catarrh, with tinnitus aurium, and slight impairment of hearing, and more recently had begun to suffer from feeble digestion. He noticed that after indulgence in certain articles, there would be abdominal discomfort, and at the same time marked exacerbation of the naso-pharyngeal catarrh. So long as the offending substance was in the stomach there was only a slight sense of discomfort, but in the course of three or four hours, a slightly painful peristaltic movement would set up in the bowels, and simultaneously the secretion from the vault of the pharynx would become unpleasantly active, and the tinnitus would increase. This condition would last for an hour, and then the naso-pharyngeal cararrh would return to its usual state. These attacks were accompanied with the escape of large quantities of gas by eructation. In many patients, usually men, between forty and sixty years of age, where we have reason to believe that the gastro-intestinal tract is habitually in a state of greater or less irritation, we find the faucial mucous membrane red and swollen. In these cases the disease which claims chief attention is the gastro-intestinal affection.

Reflex influences involving the vault of the pharynx and the ear may emanate from more distant sources. A lady of forty years of age complained of distressing tinnitus involving both ears. There had been mild naso-pharyngeal catarrh from time to time for many years. At times she was almost entirely free from tinnitus. I always succeeded in giving prompt relief by applying a moderately strong solution of silver nitrate with a mop of absorbent cotton to the vault of the pharynx. After a time this failed to give relief. It was then learned that for many years, she had suffered with pain in the pelvic regions and back, and at this particular time she was suffering in a more marked degree. A specialist was then consulted, and it was found that there was retroversion of the uterus, and subacute parametritis. These conditions were removed, aad the tinnitus disappeared without treatment to the vault of the pharynx.

The author states that he had spoken of these as indirect causes, that is, as factors competent to aggravate a preëxisting, but perhaps latent catarrhal disease, but he saw no reason why these reflex influences may not in certain cases play the part of direct exciting causes. He considered it impossible to demonstrate the correctness of this belief, and therefore preferred to adopt the view which assigns to them a less independent rôle.

DISCUSSION.

Dr. J. G. Tansley, New York. I meet with many cases of naso-pharyngeal catarrh in young girls, fifteen to twenty years of age, who are decidedly anæmic and chlorotic, and who suffer with constipation; and I have found that this was the cause of the catarrhal symptoms.

Dr. S. O. Risley, Philadelphia. It is pretty generally admitted that nasal and pharyngeal diseases are especially liable to occur in persons of a gouty diathesis. Naso-pharyngeal disease is one of the most uniform manifestations of lithæmia; from the symptoms detailed in regard to the first case of Dr. Buck, I should suggest that the digestive disturbances was probably associated with a lithæmic condition.

Dr. C. H. Burnett, Philadelphia. I have seen a number of cases without deafness, due entirely to dyspepsia. The use of nitrate of silver has been referred to. While this may be of service in other locations, I think that it is the worst application that can be made to the nose or the naso-pharynx. Its use will be followed sooner or later by sclerosis and atrophy. It will apparently cure a hypertrophic catarrh, but the case comes to the rhinologist later with a marked atrophic process in the mucous membrane. I have entirely abandoned the use of nitrate of silver in affections of the nares.

Dr. S. Sexton, New York. I have seen many cases in which irritation in the mouth has been the cause of naso-pharyngeal catarrh and aural symptoms. A lady was brought to me with intense pain in the ear and the head. There was nothing in the condition of the ear to account for these symptoms. Examination of the mouth showed that she was wearing a plate to bring the teeth closer together. The gum was intensely inflamed although the patient complained of no discomfort. The removal of the plate caused a disappearance of the pain in the ear and head. I have seen many such cases.

Dr. J. O. Tansley, New York. I have seen many cases in which irritation of the teeth caused aural symptoms. I agree with Dr. Burnett that nitrate of silver should not be used in the nasal cavity. I have not made such an application for a number of years. There is in catarrh an increased thickening of the basement membrane; this tends to contraction, and the tendency to contraction is increased by the use of nitrate of silver. I employ such agents as induce an exosmosis.

Dr. J. F. Noyes, Detroit. This paper brings up the fact that it is important that in our special practice we should consider general practice. I have always recognized these so-called reflex causes, and have treated cases by searching out these causes. A remarkable case came under my notice of a lady who after confinement developed naso-pharyngeal catarrh.

There was profuse secretion; the trouble continued for a year in spite of treatment. Finally she passed into the hands of a gynæcologist and the cause was then discovered, and treatment of the uterine disease cured the naso-pharyngeal disease.

DR. SAMUEL THEOBALD, Baltimore. I think that where atrophy follows hypertrophic catarrh it is the result, not of the application of nitrate of silver but of the continuance of the catarrh. I question whether a solution of nitrate of silver, ten to fifteen grains to the ounce, will produce sloughing. I regard this agent as a valuable application in disease of the nasal membrane.

DR. CHAS. J. KIPP, Newark. I agree with Dr. Theobald as to the value of nitrate of silver. I rarely use it in a stronger solution than twenty grains to the ounce and neutralize it afterwards by salt water.

DR. HENRY D. NOYES, New York. I have frequently noticed the connection between the lithæmic condition and certain affections not only of the naso-pharynx but also of the external auditory canal. There are certain eczematous conditions associated with the gouty diathesis.

DR. F. P. CAPRON, Providence. I have seen a number of cases of so-called hay-fever in which the premonitory symptoms were those of indigestion; for two or three weeks before the time of the onset of the regular attack, the patient would complain of digestive disturbance.

(To be continued.)

AMERICAN OPHTHALMOLOGICAL SOCIETY.

TWENTY-FOURTH Annual Meeting, held at the Pequot House, New London, Conn., July 18 and 19, 1888.

WEDNESDAY, FIRST DAY. MORNING SESSION.

The Society was called to order by the PRESIDENT, DR. W. F. NORRIS, of Philadelphia. The deaths of Dr. C. R. Agnew, Dr. E. G. Loring and Dr. Joseph Aub, were reported.

Dr. H. P. NOYES, New York, read a memorial of the late Dr. C. R. Agnew.

Drs. W. H. Caswell and C. S. Bull were appointed a committee to preface an appropriate minute in regard to the death of Dr. E. G. Loring, and Dr. Charles J. Kipp was appointed to preface a similar minute in regard to the death of Dr. Joseph Aub.

The members of the American Otological Society were invited to take seats with the Society. The following gentlemen were invited to take part in the discussion, Dr. Koler (Vienna), Dr. Skinner and Dr. Nodine.

A CONTRIBUTION TO THE TREATMENT OF MEMBRANOUS OPACITIES IN THE VITREOUS,

by DR. C. S. BULL, New York.

These opacities in the form of membranes or shreds are rarely freely movable, and usually resist internal treatment. Operation by incision with a needle was first performed by Von Graefe. In the experience of the writer the operation had been found useful. Some opacities as a result of hæmorrhage or inflammation of the choroid sometimes respond to internal remedies, but as a rule these failed. By incision of the membrane a direct improvement of vision may be obtained and the process of absorption may be stimulated. Posterior opacities are more easily reached, with less danger to the lens and with more favorable results, than in the case of anterior opacities. The author has done this operation in seventeen cases of chronic membranous deposits in the vitreous. In some cases the ordinary decision needle was used; in others a broader needle and in a few a slender cataract knife. Cocaine was employed in all cases. The point selected by preference for the introduction of the needle was just in front of the equator of the eye and below the insertion of the external rectus muscle. There seems in this operation to be no danger of loss of vitreous through the small opening, nor is there danger of hæmorrhage. The puncture should be posterior to the ciliary process and pressure with the forceps should be avoided. Little or no reaction follows the operation as a rule. A protective bandage is required only a few days. Antiseptics were employed in all cases.

The details of the seventeen operations on fifteen patients were given. Fourteen showed decided improvement in vision. Three were failures. There was no loss of vision from the operation in any case. The operation is appropriate in certain cases, but it is wise to wait until all inflammatory symptoms have subsided before attempting any operative procedure. The eye should be absolutely free from all irritation before surgical interference is attempted.

DISCUSSION.

DR. W. F. MITTENDORF, New York. I think that vascularity of the vitreous membrane should always speak against operations of this kind. Vascularity even if all inflammatory signs have subsided, points to a fatal prognosis.

A CASE OF PULSATING EXOPHTHALMUS CURED BY LIGATION OF THE COMMON CAROTID,

by DR. F. BULLER, Montreal.

Pulsating exophthalmus occurring spontaneously or as a result of traumatism is rarely met with. The pathology is so well understood that little remains to be done in this direction at the present time. In the matter of treatment, there is no rule so firmly established but that much must be left to the judgment and discretion of the surgeon.

The author had seen four cases of this affection. In the first the condition followed a blow upon the head. Some months after the appearance of the pulsating exophthalmos, ligation of the carotid was performed, but the patient died in the course of a few weeks from repeated attacks of epistaxis.

The second case has already been reported.

In the third case the affection followed a blow on the brow from a piece of iron. The patient was seized with severe epistaxis and died in a few minutes. There was found a depressed fracture of frontal bone with a fissure extending across the orbital roof and body of the sphenoid bone directly beneath the cavernous sinus. As a result of caries of the bone there was a direct communication between the nasal cavity and the internal carotid artery.

The fourth case, the subject of the paper, came under observation May 24, 1888. A young man aged twenty-eight, fell a distance of twenty feet, striking the right side of head, rendering him unconscious for twenty-four hours. After the swelling had subsided the patient noticed diplopia, one image being higher and less distinct than the other. There was also a

loud beating sound in the right ear. Two weeks before coming under observation, prominence of the eye was noticed. There was still diplopia, the higher image moving up and down with each heart-beat. Four days before coming under notice, the pain became intense. On examination there was at the inner extremity of the right brow a swelling which imparted a distinct thrill to the finger. There was also a harsh bruit. Pressure over the common carotid diminished the intensity of the thrill and lessened the pulsation.

It was decided to ligate the common carotid in the upper part of its course, and this was done May 25th, two ligatures being applied and the vessel divided between them. The immediate effect was softening of the swelling, partial reposition of the eye-ball, great diminution in the pulsation and disappearance of the bruit. The patient made a good recovery and left the hospital with very little prominence of the ball. V = $\frac{20}{20}$: movements normal.

PULSATING EXOPHTHALMUS,

by Dr. Charles J. Kipp, Newark.

A lady, seventy-six years of age, presented herself with the history that shortly after striking the head in a fall she noticed noise in both ears, followed by protrusion of both eye-balls, the right $\frac{4}{10}$ inch; the left $\frac{3}{10}$ inch. There was no marked pulsation, but there was a thrill and a bruit could be heard over the anterior half of the head. This could be arrested by compression of the right carotid and partially so by compression of the left carotid. In view of the age of the patient, no radical measures were recommended, but it was suggested that pressure be made on the right carotid as often as convenient. Iodide of potassium was also given. Three months later the patient stated that the noise had suddenly disappeared. This was followed by disappearance of the exophthalmus first in the left eye and subsequently in the right. The external appearance of the eyes are now normal. There is, however, a marked pulsation of the right subclavian artery, but no aneurism can be discovered.

DISCUSSION.

Dr. S. D. Risley, Philadelphia. I would call attention of the Society to the fact that Dr. Harlan reported a case of this kind cured by compression, and that I also reported a case in which compression of the vessel for a short time was followed by disappearance of the symptoms and subsidence of the exophthalmus.

AN ANALYSIS OF 576 CASES OF THE REFRACTION OF HEALTHY HUMAN CORNEÆ, EXAMINED WITH THE OPHTHALMOMETER OF JAVAL AND SCHIOTZ,

by Dr. Swan M. Burnett, Washington.

These 576 corneæ belonged to 301 persons examined within a little over a year by Dr. Burnett. Pathological states of the cornea were excluded for consideration at another time. The corneal refraction was found to be the same in both eyes to within 0.25 D. in 110 persons. The horizontal meridian (to within 5°) was the least refractive (astigmatism according to the rule) in 420 eyes. The vertical meridian was the least refractive (astigmatism against the rule) in 20 eyes. In 88 eyes the meridians were oblique. In 58 eyes, the difference in the refraction of the two meridians was less than .25 D. In 101 eyes there was *emmetropia*. The largest number has a corneal refraction of from 44 D. to 45 D.; the next largest from 43 D. to 44 D. The strongest corneal refraction was 47 D., the weakest 39 D. In 55 eyes, there was *simple myopia*. The strongest refraction in the weakest meridian was 47.25 D.; the weakest 39 D. The corneal refraction did not in any considerable number of cases bear any close relation to the degree of the myopia. *Simple hypermetropia* was present in 59 eyes. Weakest refraction in the weakest meridian was 40.5 D.: the strongest 46 D. As in myopia, the corneal refraction was no indication as to the degree of general hypermetropia, *myopic astigmatism* was found in 140 eyes. In 4 eyes, the general astigmatism was greater and in 11 it was less than the corneal. In 14 eyes, the difference in the axes of the corneal membrane and that of the prescribed glasses was greater than 5°. *Hypermetropic astigmatism* was present in 96 eyes. In 4 eyes, the corneal astigmatism was greater and in 2 eyes it was less than the general. The axes corresponded in all but 9 eyes. *Compound myopic astigmatism* existed in 63 eyes. In all but 7 eyes the corneal and general astigmatism corresponded and in 44 eyes the axes corresponded. *Compound hypermetropic astigmatism* was found in 55 eyes. In 31 corneal and general astigmatic meridians corresponded. The corneal and general astigmatism was the same in all but 4 eyes, *mixed astigmatism* was present in 8 eyes. In 4 the corneal and general astigmatism was the same. In 2 the corneal was less and in 1 greater than the general. The corneal and general astigmatic meridians were the same in 5 eyes.

In 42 eyes the general astigmatism was against the rule, while in only 18 *of these eyes* was the corneal astigmatism against the rule. From examinations under a mydriatic the author felt himself warranted in thinking that many cases of lenticular astigmatism are due to an oblique position of the lens.

Corneal astigmatism is, with very few exceptions, according to the rule (vertical meridian, the stronger). From a study of these statistics the author feels warranted in concluding that while the corneal refraction gives no indication of the general refraction of the eye, its astigmatism in the vast majority of cases, expresses the general astigmatism both as to degree and direction of its axis, and considers, therefore, the instrument of Javal and Schiotz one of, if not the most important instrumental means for the diagnosis of the anomaly. He does not think astigmatism more productive of progressive myopia than other forms of ametropia.

DISCUSSION.

Dr. H. D. Noyes, New York. I have used the ophthalmometer of Javal and Schiotz with great satisfaction. In the immense majority of cases the evidences of the ophthalmometer without the use of atropine have corresponded with the evidences of the trial case. The amount of astigmatism and in a general way the axis of the astigmatism is obtained. The use of this instrument has led me to believe that mixed astigmatism is more common than we usually imagine. I have also noted the influence of the eyelids in altering the curvature of the cornea. I have also satisfied myself that the tension of the eye-muscle modifies the curvature of the cornea. I have also noticed in some cases a pulsation of the corneal reflex due to the fact that the cornea was so thin that the

circulation of the eye impressed itself upon it. This I have seen particularly in conical cornea. The use of this instrument does away to a large extent with the necessity for the employment of atropine.

DR. SAMUEL THEOBALD, Baltimore. I infer that the author thinks that when a midriatic is employed, the lenticular astigmatism is done away with. My experience leads me to believe that the asymetrical condition in the lens, does not at once disappear on paralysis of the ciliary muscle. I think that the discrepancy between the total and general astigmatism may often be accounted for by this persistent asymetrical condition of the lens. This condition gradually disappears after suitable glasses are worn.

DR. B. ALEX RANDALL, Philadelphia. I cannot agree with the author that simple astigmatism is so common and predominates over other forms. Taking the records of the Hospital of the University of Pennsylvania for the last ten years, I find 4,000 refraction cases determined almost without exception under a midriatic. Compound hypermetrophic astigmatism constituted about 40%; compound myopic astigmatism constituted 30%; simple myopia and hypermetrophia about 8% and 12% respectively; mixed astigmatism only about 1 or 2%; compound astigmatism constituted at least 70% of the total number of cases.

PROGRESSIVE HYPERMETROPIC ASTIGMATISM,

was the title of a paper read by DR. J. B. EMERSON, of New York.

DR. EDWARD JACKSON, Philadelphia, exhibited a new form of Cataract Knife. It was designed to combine the advantages of the Græfe and Beer knives. The point, resembling that of the Græfe knife, allowed the puncture and counter-puncture to be made in the same way as with the Græfe knife; while the rest of the blade having the shape of Beer's knife enabled one to complete the incision as with that instrument. With it the puncture and counter-puncture are completely under control, the flap is completed at a single thrust, the aqueous is not lost until the incision is nearly finished and the counter-pressure by the back of the knife assists in steadying the eye.

DR. J. O. TANSLEY exhibited the following instruments: An improved Lachrymal Syringe, in which the nozzle ends in a closed bulb, the opening being on the sides of the tube; a Clamp to prevent the passage of atropine solutions through the lachrymal duct into the nose in cases where the free use of atropine is called for; an improved Lachrymal Probe, and improved Style.

DR. SAMUEL THEOBALD exhibited Probes made of aluminium.

ŒDEMA OF THE CHOROID AND RETINA,

by DR. EDWARD JOHNSON, Philadelphia.

The author reported the case of a young man struck in the eye with a marble or small stone causing a bruise of the eye-ball. The ophthalmoscope showed localized swellings of the choroid and retina, at the posterior pole of the eye; the choroidal spots having the usual grouping of ruptures of the choroid in that region. These spots disappeared in about a week. There was also at first some 0.75 D. myopia astigmatism which gradually diminished, and in three weeks entirely disappeared, leaving the sight perfect.

SYMPTOMATIC MYOPIA,

by DR. W. F. MITTENDORF, of New York.

But little attention has been called to myopia as a symptom of various affections of the eye. Three forms of myopia may be spoken of, axillary, refractive, and symptomatic. The latter form may be caused by traumatism, but more commonly by diseased conditions. It may be produced by displacement of the lens forward. More frequently it is due to swelling of the lens accompanying beginning cataract. This is sometimes relieved by the use of concave glasses; very strong glasses being occasionally required. Plastic exudations may also cause myopia, but these usually so interfere with vision that it is impossible to demonstrate the existence of myopia. Glaucoma, serous choroiditis and iritis are frequently accompanied with myopia as a symptom. A number of illustrative cases were cited. In these cases the myopia is not permanent but as the disease disappears, the myopia passes away, leaving the refractive condition of the eye the same as before the attack.

DISCUSSION.

DR. J. O. TANSLEY, New York. Some years ago, I reported a case of localized exudative choroiditis just beneath the macula, with myopia. The myopia gradually increased as the attack reached its height and as the inflammation subsided, the myopia passed away.

DR. CARL KOLER, Vienna. I think that in these cases of myopia in iritis, the condition may be due to the irritation of the ciliary muscle. There is hyperæmia of the ciliary body, and as the irides are contracted, it is to be supposed that the ciliary muscle is also contracted. Although atropine may be used there is not full dilatation of the irides. It is, therefore, reasonable to suppose that the myopia is a result of spastic contraction due to inflammation.

DR. S. D. RISLEY, Philadelphia. In a few instances it has seemed to me that in these cases of iritis and choroiditis the myopia was due to the dread of light and the cramp of the lids.

DR. JOHN GREEN, St. Louis. In two attacks of iritis of which I was myself the subject, I carefully studied this myopia. In my case the eyes were completely under the influence of atropia. The pupils were dilated and the ciliary muscles paralyzed.

Adjourned until 8 P. M.

(To be continued.)

— The annual meeting of the Rhode Island Medico-Legal Society was held July 19, 1888. The following officers were elected: *President*, Dr. G. D. Wilcox; *Vice-President*, Dr. J. H. Morgan; *Secretary* and *Treasurer*, Dr. F. B. Fuller. A paper entitled "Belgium and her Insane Institutions," was read before the Society, by Clark Bell, Esq., of New York.

— The *St. Louis Medical Journal* is also among the prophets. Among its aphoristic maxims are the following: The physician who values his time and advice is the man who is appreciated. He who sells himself for nothing generally gets all he is worth. He who goes for half-price, when patients are able to pay a reasonable fee, goes for more than he would bring on the market. A community never values a physician higher than he values himself. He who works for love may gain the reputation of a good Samaritan, but good Samaritans are not all good doctors.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 26, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

THE FOURTH YEAR AT THE HARVARD MEDICAL SCHOOL.

It has been an interesting question among those anxious for the welfare of the Harvard School, but not informed as to its plans, what course would be adopted as to its fourth year. The recommendation by the faculty of a four years' course has not hitherto met with an encouraging response on the part of the students. Some few have seen the advantage of the more extended course of study, but the fourth-year class has not increased in numbers nor in scholarship, and no great progress has been made towards the establishment of a compulsory four years' course. Certain changes in the curriculum are already announced which seem calculated to make a very desirable change. The faculty retain the recommendation of four full years of study, and still expect that the time may not be very far distant when four years shall be compulsory. The changes are mainly in accord with the dominating idea at Harvard, of allowing the student an election in his courses of studies, though fortunately the existing three years' curriculum is not disturbed.

In addition to the existing requirements for the third-year degree, each candidate will be obliged to take examinations from a list of elective studies, to be chosen at the commencement of the year. He may choose to pass an examination of two hours in either of the following subjects, — Dermatology, Diseases of the Nervous System, Diseases of Children, or Gynæcology: or he may pass two examinations, of one hour each, in any two of the following subjects, — Ophthalmology, Otology, Mental Diseases or Legal Medicine.

The course of study for the fourth year will be entirely elective. To obtain the fourth-year degree each candidate must pass examinations amounting to ten hours chosen from the following list of studies, the choice to be made at the commencement of the year and to be regarded as final —

Examinations of two hours each in Ophthalmogy, Dermatology, Otology, Clinical Obstetrics, Gynæcology, Diseases of Children, Diseases of Nervous System; of one hour each in Mental Diseases, Laryngology, Operative Obstetrics, Operative Surgery, Legal Medicine, Hygiene, Bacteriology. The above are entirely distinct from the third-year courses of the same title, and in addition there will be given clinical and laboratory courses in Orthopædic Surgery, Genito-urinary Diseases, Syphilis, Ovarian Tumors, Clinical Microscopy, Preparation of Food for Infants and Invalids; in these courses no examination is required.

The hospital service in Boston differs from that of many cities in that candidates for hospital positions are required not to have received their medical degree. Such positions are awarded after a competitive examination, for the most part, and are usually taken at the close of three years of study. The successful candidates for these positions have usually taken later the degree of the three years' course, though evidently among the best of the students: a condition which has without doubt done something to render the fourth degree less popular. For the future the fourth-year degree is attainable by hospital internes under the following conditions:

House-officers in the Massachusetts General Hospital, Boston City Hospital, Carney Hospital, McLean Asylum, Massachusetts Charitable Eye and Ear Infirmary, Boston Children's Hospital, and Free Hospital for Women, may obtain the fourth-year degree by entering the fourth class, passing an examination in the elective amounting to five hours, and presenting a certificate of satisfactory performance of duty in the hospital for a period equivalent to the school year, and an acceptable thesis or clinical report based upon observations made during their service. On account of the shorter services in the Lying-In Hospital and Adams Nervine Asylum, internes of these institutions will be required to pass an aggregate of seven hours examination, and present a certificate and thesis as above.

Provision is also made for students who desire to devote their fourth year to special Laboratory Work, and the fees of the fourth year are diminished by one-half to men who complete four years in the school and to a nominal sum for hospital house-officers.

This course has not been elaborated without the careful consideration of other plans. It will doubtless prove attractive to many who failed to be attracted by the very laborious courses previously presented. It is to be expected that its numbers will be recruited from the start from the hospital internes, and it certainly presents on paper a plan which bids fair to be successful. The elective system is given a sufficient representation in the new plan; to allow it to interfere with the studies hitherto required in the first three years would certainly be a mistake.

HYPERTENSION OF THE ARTERIES: THERAPEUTIC INDICATIONS. II.

In angina pectoris, there is exaggerated and permanent arterial tension, and here, as in instances cited in the former paper, the beneficial influence of cardio vascular depressants, such as nitrite of amyl, glenoine, morphine, which open up the capillary sluiceways of the organism, is seen, while digitalis which raises arterial pressure, but aggravates the condition.

Permanent hypertension has been supposed by some excellent authorities to belong exclusively to

Bright's disease or to that form of the latter known as interstitial nephritis. As the older theory puts it, the heart is overworked, owing to the obstruction in the renal circulation, and hypertrophies; more work is also imposed on the arterio-capillary system, and changes in the arteries and minute vessels take place (increase of muscular tissue, fibroid thickening). This theory was eventually abandoned for what is now known as the "stop-cock theory," which makes both heart and arteries hypertrophied in a constant antagonistic struggle, the heart laboring to force into the tissues blood poisoned by waste elements which the kidneys, being diseased, have failed to eliminate, the arteries contracting preternaturally in the endeavor to shut the blood out of the tissues. A third theory which has had many advocates, notably Mahomed, who defends it in his treatise on "Chronic Bright's Disease without Albuminuria," and other papers, regards certain generalized circulatory changes, a condition known as arterio-capillary fibrosis, as primary, and Bright's disease only as one expression of this alteration of the bloodvessels. Without doubt this is an extreme view; there is too much evidence that in very many instances the renal disease comes first, and the arterial lesions are secondary to blood changes therefrom ensuing. The existence, however, of a general arterio-capillary fibrosis, apart from any renal affection, or at least, anterior to such affection, is very probable, and Huchard in the paper referred to last week, and to which we have again to call attention, presents some weighty considerations in support of his proposition that "arterial hypertension is the cause of the arterio-sclerosis, preceding for a considerable time the evolution of divers maladies (cardiopathies and arterial nephritis) which are themselves dependent on the vascular sclerosis." The order of facts is this: arterio-capillary spasm, arterial hypertension, arterial sclerosis, visceral sclerosis. Huchard cites instances where the long precedence of the arterial condition seemed clear to him; where for years there were the signs of exaggerated arterial tension (the sphygmographic tracings, the diastolic resonance of the aorta, the dyspnœa of exertion, etc.), then finally all the symptoms of interstitial nephritis manifested themselves. Such cases are often attended with considerable œdema of the lower extremities long before there is a trace of albumen in the urine. Here are witnessed the benefits of an exclusive milk diet, of iodide of sodium, of trinitrine, which often bring down arterial tension from 27–30 to 20, or even below this figure, as is shown by the sphygmomanometer. By such treatment the worst issues are often staved off for years, or kept permanently in abeyance.

The pathogeny of arterial hypertension is to be sought in the state of the heart, of the blood, or of the vessels. As for the influence of the heart, this would seem to be very limited, as, in this writer's estimation, it is doubtful if cardiac hypertrophy ever precedes a condition of arterio-capillary fibrosis.

The quantity and quality of the blood, Huchard thinks, have a restricted but real influence. If the water of the blood is augmented (serous plethora), arterial hypertension must ensue. The quality of the blood has a certain rôle. It is known that saturnism causes arterial hypertension; and this is undoubtedly the case with toxic products generally, which are retained in the blood through failure of the emunctories to eliminate them. But the most efficient cause of hypertension is *spasm of the arterioles and capillaries.* This may be brought about by various agencies: gout, "which is to the arteries what rheumatism is to the heart;" rheumatism; the influence of tobacco; the abuse of alcoholic stimulants. Heredity has an important predisposing influence. Overwork has undoubtedly an etiological part; and so have mental emotions, which, Huchard says, often determine attacks of vascular spasm, and contribute to produce temporary or permanent hypertension. Huchard finds arterio-sclerosis to be especially frequent among members of the medical profession: this he attributes largely to the hurry, anxiety and overwork incident to this profession.

Among the symptoms of hypertension may be mentioned the oppression, the dyspnœa on exertion, palpitations, which are often of a distressing character, local accessions of algidity, of pallor, etc. Broadbent mentions besides, a tendency to somnolence, headache, vertigo, certain neuralgias, in a word, all the morbid incidents peculiar to arterial spasm. Acute dilatation of the heart and aorta often accompany this condition of vascular hypertension; this is revealed by peculiar signs, such as the diastolic aortic resonance alluded to in the previous paper. At the same time, the precordial shock is increased, giving to the organ the character of the "impulsive heart." The beatings of the arteries are exaggerated, the radial pulse is "strong, vibrating, concentrated, tense," *corded*, as the old writers called it.

The therapeutic indications are clearly deducible from the foregoing considerations. The heart must be sustained, and the peripheral obstacles diminished: everything capable of bringing about vaso-constriction and arterial hypertension must be avoided, all medicines, for instance, such as chloral, ergot, lead, belladonna; beverages, such as tea, coffee, alcoholic stimulants; tobacco, excesses of the table, too animalized a diet; finally, excessive or depressing emotions, and overwork of mind or body.

Among medicines, such as are known to be vaso-dilators or depressors, are indicated, such as opium, aconite, trinitine, nitrite of amyl, the iodides. A mixed diet is to be recommended, such as white meats, fresh vegetables and salads, bread and fruits and milk. In some cases of great vascular fulness, abstinence from liquids, the "dry diet" of Chomel is to be advised. The functions of the skin and other emunctories should be promoted, the hours of sleep regulated, and exercise should be just sufficient: in fact, the most effective treatment is the prophylactic.

MEDICAL NOTES.

— The medical officer in charge of the Marine-Hospital Service reports from the Ship Island Quarantine Station, Miss., that the captain and four men died of yellow fever, on the Norwegian bark "*Magnolia*," on the voyage from Rio Janeiro. The vessel was bound for Pensacola, Fla., and is now undergoing quarantine at Ship Island, having been sent to that station by the Pensacola health authorities.

Two cases of yellow fever were reported at Tampa, Fla., July 16th, one convalescent, and the other probably fatal. There are several cases at Manatee. On July 19th, the governor of Florida made application to the Secretary of the Treasury for aid to the local health authorities in suppressing the disease, and the Secretary informed the Governor, that aid would be furnished through the Marine-Hospital Bureau. A house inspection at the villages named will be immediately commenced.

Seventeen deaths from yellow fever were reported at Havana, Cuba, for the week ending July 7, 1888.

The health officer at San Francisco, Cal., telegraphed under the date of July 18th: "Cholera reported epidemic at Hong-Kong." The State Department has cabled the consul at Hong-Kong to report the facts.

— We learn from an English exchange of the sad death of Mr. Edmund Gurney, Secretary of the Psychical Society, and author of "The Power of Sound" and other works. The deceased gentleman suffered from obstinate sleeplessness and occasional neuralgia, and succumbed to an overdose of chloroform which he incautiously took one evening when alone at the Albion Hotel, Brighton, whither he had gone for a night on business. This emphasizes the danger of the reckless habit of the self-inhalation of anæsthetics.

— Dr. Thomas Wood recently showed before the Obstetrical Society of Edinburgh an experiment showing that the caudal extremity of the fœtus is specifically heavier than the cephalic. (*Edinburgh Medical Journal*, July, 1888.) In a glass vessel was put a fluid composed of salt water and spirit of such a density that the fœtus which it contained neither rose to the top nor fell to the bottom, but was suspended in the centre — in fact, the specific gravities of the fluid and of the fœtus, were almost if not entirely equal. The position which the fœtus assumed, therefore, showed which is the specifically heavier end, and this, as was seen, is the caudal extremity. The fœtus floats in the fluid almost in a vertical position with the head uppermost.

— Dr. Thomas Linn, writing from Paris to the *Philadelphia Medical Times*, says, that some attention has been paid to the recent treatment by which the old Emperor of Brazil was brought out of his illness at Milan, and he is now fast recovering at Aix les Bains. It was hypodermic injections of caffeine that saved him, and in this connection it should be remembered that caffeine is an uncertain drug, that has to be given in sufficient quantity in heart failure, and yet if too much is given it may prove fatal. It is also very insoluble in most of its salts, such as the citrate, etc., and it may be well in this connection to give Dr. Huchard's formula:

℞	Caffeine.	2 grammes
	Benzoate of soda.	3 "
	Distilled water.	6 "
M	(Make the solution while it is warm.)	

From four to six injections per day, the usual syringeful used each time of this solution, is the proper dose. It will be found to act as a general tonic, a cardiac tonic, and above all as a *diuretic*, being perhaps the best of all for this purpose. The salts of caffeine are not used here now at all but the drug itself combined with benzoate of soda to make it soluble.

— Dr. Richard J. Levis in his presidential address on the "Traditional Errors of Surgery," (*Philadelphia Medical Times*, July 21st,) before the Medical society of Pennsylvania, tells some truths which are not gratifying about professional prejudice, especially in connection with the subject of ether anæsthesia, and ovariotomy. As to the former, he quotes from the *Philadelphia Medical Examiner*, 1846:

"We should not consider it entitled to the least notice but that we perceive, by the *Boston Medical and Surgical Journal*, that prominent members of the profession in that city have been caught in its meshes. We are persuaded that the surgeons of Philadelphia will not be seduced from the high professional path of duty into the quagmire of quackery by this will-o'-the wisp. We cannot close these remarks without again expressing our deep mortification and regret that the eminent men who have so long adorned the profession in Boston should have consented for a moment to set so bad an example to their younger brethren, as we conceive them to have done in this instance. If such things are to be sanctioned by the profession, there is little need of reform-conventions or any other efforts to elevate the professional character. Physicians and quacks will soon constitute one fraternity."

Regarding the infant operation of ovariotomy, Professor Charles D. Meigs thus emphatically expressed himself: "I detest all abdominal surgery." "I am free to say that I look upon all operations for the extirpation of the diseased ovary as not to be justified by the most fortunate issue in any ratio whatever of the cases." "Dr. Atlee's coolness in cutting open a woman's belly does not, I think, entitle him to judge more clearly than I, as to the morals of such surgery. . . Dr. Atlee likes ovarian operations; on the contrary I detest them, and should be glad to see them prevented by statute."

. . . "I should be glad if you would look over the statistics of ovariotomy to discover how many bellies have been ripped up by the surgeons in the expectation of having the blessed satisfaction and *praise* of curing a tumor. Suppose a surgeon to open a woman's belly to extirpate an ovary; that he finds no ovary there; that he then sews up the gash; and next, that

she dies! What should the attorney-general say? It would scarcely be unfair to say, of all the fatal results of operation for extirpation of the ovary, that the patient is compelled to render her soul to God, and her carcass to the surgeon."

NEW YORK.

— Some alarm was recently caused by the appearance of small-pox among the patients in the city insane asylum on Ward's Island; but the most vigorous measures were at once taken to prevent the spread of the disease, including a general vaccination of the inmates. Five cases in all were removed to the small-pox hospital on North Brothers Island, and it is probable that no additional cases will now develop. The disease appears to have been carried from the city by some of the attendents in the asylum.

— The Health Department has issued a notice calling attention to the fact that a large proportion of the records of births, marriages and deaths received for filing in the Bureau of Vital Statistics are written in aniline inks, which will be illegible in a few years. The Board therefore requests that in documents sent them, only good and permanent black ink be used.

Miscellany.

THE HARMLESSNESS OF CERVICAL LACERATIONS.

DR. EMIL NOEGGERATH has attacked an article of the gynæcologists' creed in the following radical utterances: —

(1) Women with uterine disease conceive more easily if the cervix is lacerated than if it is intact. They abort less often in the first condition than in the second.

(2) The position of the uterus is not influenced by cervical laceration.

(3) The uterine axis is not lengthened by cervical laceration.

(4) Erosions and ulcerations are equally frequent in lacerated and in intact cervices.

(5) Erosions of the lips are never the direct result of cervical laceration.

(6) Disease of the tissues of the cervix are not more frequent in lacerated than in uninjured cervices.

(7) Cervical tears have no influence on the development of uterine disease either as to intensity or frequency.

In his concluding remarks he recommends that lacerations and tears be left alone.

LABORATORIES AND MUSEUMS OF HYGIENE FOR TEACHING PURPOSES.

DR. PROUST, the Professor of Hygiene in the Faculty of Medicine, Paris, recently gave a lecture congratulating the students that this school is at last to have a laboratory and museum specially designed for use in the teaching of practical hygiene.

The model for buildings of this kind has been the institute built and equipped by the University of Munich for the use of Professor Von Pettenkofer. Laboratories specially devoted to giving instruction in hygiene now exist in Berlin, Leipzig, Göttingen, Buda-Pesth, Amsterdam, and in connection with the medical faculties of most of the great universities. Of these the largest and most completely equipped is that at Berlin, under the direction of Dr. Koch, which has in connection with it a large museum containing most of the exhibits which were in the Berlin Exposition of Hygiene in 1883.

In France the organization of such an institution is just beginning, Dr. Proust stating that thus far he has had at his disposal neither laboratory nor museum nor assistance or material of any kind in teaching.

In this country the first steps towards the organization of a laboratory and museum of hygiene have been taken at the School of Mines of Columbia College in connection with the departments of chemistry, engineering, and biology, and similar materials exist and are used in the Massachusetts Institute of Technology.

The amount and variety of apparatus, models, etc., required for effective teaching in practical hygiene, whether this instruction is to be given to medical students or to architects and engineers, is very considerable, but it is in every way worth its cost, and the institution which is best provided with such material is the one which, in the long run, will succeed the best. For the last few years the tendency has been to consider a laboratory of hygiene as synonymous with a bacteriological laboratory, and for this there was good reason. There are, however, many problems to be worked out in the former which find no place in the latter, and while the hygienic laboratory must include all the means of bacteriological research, it should also contain many things whose relations to bacteria are very remote.

The only museum specially devoted to hygiene which we have in this country is the one under the direction of the Medical Department of the United States Navy in Washington. This contains a large amount of interesting material brought together by the first director of the museum, Dr. J. M. Browne, who is now Surgeon General of the Navy, but it is not well housed, being overcrowded, and is not located where it would be of the most interest. It is not at present used for teaching purposes.

It seems not improbable that a well-equipped laboratory and good museum for instruction in practical sanitation will be soon formed at the School of Mines in New York where it is needed and will be most useful, and it is probable that in all our technological schools such institutions will soon be developed.

To what extent practical instruction in hygiene is given in medical schools in this country we do not precisely know. Many of them have courses of lectures on hygiene given to the students; we believe that in the course of these lectures a few specimens of plumbing fixtures, good and bad, are occasionally shown, and bacteriological instruction is now given in the better class of medical colleges, but no one of our medical schools has anything comparable with Pettenkofer's Institute at Munich.

It is safe to predict that there will soon be a change for the better in this respect, and that the larger and more reputable schools will find that they cannot afford to neglect this branch of study as they have done in the past. — *The Sanitary Engineer*, July 14.

THE ELIMINATION OF MERCURY.

M. F. BALZER and Mlle. A. Klumpke during the past year have made a long series of observations at the Lourcine Hospital, in Paris, on the amount and rapidity of the elimination of mercury by the urine during a treatment of long standing. (*Revue de Med.*, April 1888, and *Practitioner*, June 1888.) The condition of the mercury in the system, in whatever form it is administered, is according to some authors the bichloride held in solution by albumen or sodium chloride, or perhaps more accurately an albuminate of the oxide of mercury united with sodium chloride. Others, again, show some cause for thinking that metallic mercury in a state of extreme division is precipitated by hæmoglobin and circulates in the blood. The point cannot be considered settled. It accumulates in all tissues, but more especially in the liver and kidneys. It is eliminated almost entirely in the urine, but is also found in the saliva, sweat, fæces, and, which is an important point, the milk. There are many methods for the estimation of mercury in organic fluids; M. Balzer and Mlle. Klumpke have throughout adopted that of Witz, as modified by Souchow and Michaelowsky, which permits of the easy detection of a thousandth of a grain in an ounce. After a single dose of mercury its elimination is rapid and seems complete in twenty-four hours. If a continuous treatment is interrupted its excretion continues for some time after the interruption, and it has been found in the liver as much as a year after its administration has been stopped (Kussmaul, Gorup-Besanez). During a continuous treatment by equal daily quantities of mercurial ointment, Michaelowsky found from 1,500 analyses of the urine in seventy-four cases, that the amount eliminated gradually increased along with the length of time the treatment had been used, but became nearly constant after about a month. Souchow showed the same thing during a treatment by injections. After either treatment had been continued for some months and then been stopped, slow elimination went on for from six to nine months. It is sometimes desirable to hasten this final elimination, and potassium iodide has been thought to be of use. But this is at least doubtful, and hot air baths producing much diaphoresis have been found of more service. The amount of mercury that can be steadily eliminated for many weeks from the kidneys when the body is saturated is about a sixteenth of a grain (0.06 gramme). Less than half this quantity is excreted by the salivia; and the remainder, if there is any, passes with the intestinal excreta and may give rise to diarrhœa. The practical conclusion to be drawn from these minute researches is that it is well to stop the administration of mercury when the amount eliminated by the urine has reached its normal maximum, for neither abnormal polyuria can be counted upon to carry it off, nor is its passages by other channels likely to be innocuous.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 14, 1888.

Deaths reported 2,708: under five years of age 1,399; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 980, consumption 263, acute lung diseases 124, diarrhœal diseases 744, diphtheria and croup 79, whooping-cough 33, typhoid fever 29, measles 24, scarlet fever 18, puerperal fever 15, cerebro-spinal meningitis 12, malarial fever 11, erysipelas eight, small-pox (Philadelphia) seven. From typhoid fever, Philadelphia 13, St. Louis four, New York three, Boston and Salem two each, Baltimore, Washington, Pittsburgh, Charleston and New Bedford one each. From measles New York 19, Philadelphia, St. Louis, Baltimore, Cincinnati, and Washington one each. From scarlet fever New York 15, Baltimore and Cambridge one each. From puerperal fever, New York eight, St. Louis five, Charleston and New Bedford one each. From cerebro-spinal meningitis, New York, St. Louis, Washington, Worcester and Somerville two each, Cincinnati and Nashville one each. From malarial fever, New York and St. Louis three each, Baltimore two, Cincinnati, Charleston and Fall River one each. From fevers, New York six, Boston and Pittsburgh one each.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending June 30th, the death-rate was 15.9. Deaths reported —— : infants under one year of age 2,864; acute diseases of the respiratory organs (London) 156; whooping-cough 85, diarrhœa 73, scarlet fever 43, diphtheria 34, measles 32, fevers 22, small-pox (Preston 11, Sheffield three, Hull one,) 15.

The death-rates ranged from 10.4 in Brighton to 27.8 in Preston: Birmingham 14.2: Blackburn 14.5; Bradford 15.0; Hull 14.7; Leeds 15.3; Leicester 15.3; Liverpool 16.1; London 15.1; Manchester 21.2; Nottingham 15.1; Sheffield 17.0; Sunderland 13.4.

In Edinburgh 16.9; Glasgow 21.7; Dublin 24.8.

The meteorological record for the week ending July 14, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, July 14, 1888.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.		Velocity of Wind.		State of Weather.[1]		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 21, 1888, TO JULY 27, 1888.

McPARLIN, THOMAS H., surgeon United States Army. Leave of absence extended one month. Paragraph 10, S. O. 160, Department of the Platte.

WOLVERTON, WILLIAM D., surgeon United States Army. Leave of absence extended twenty days. S. O. 142, Headquarters Division of the Atlantic.

CORSON, JOSEPH K., assistant surgeon United States Army. Leave of absence for one month with permission to apply for an extension of one month. S. O. 78, Headquarters Department of the Columbia, Vancouver Barracks, W. T., July 13, 1888.

DAVIS, WILLIAM B., captain and assistant surgeon United States Army. Will proceed to Fort Niagara, N. Y., for the purpose of completing his target practice for this year with Co. C, 23d Infantry. Upon completion of this duty Capt. Davis will return to Fort Porter, New York. S. O. 145, Headquarters Division of the Atlantic, Governor's Island, New York City, July 17, 1888.

WOOD, LEONARD, first lieutenant and assistant surgeon United States Army, is relieved from duty at Fort Huachuca, Ariz. T., to take effect at the expiration of his present leave of absence, and will report to the commanding officer at Fort McDowell, Ariz. T., Paragraph 14, S. O. 162, A. G. O., July 14, 1888.

APPOINTMENT. HARVARD UNIVERSITY.

The appointment of Dr. T. M. Rotch as Assistant Professor of Children's Diseases was inadvertently omitted from the list of appointments published a few weeks ago.

ERRATUM.

In the last JOURNAL, on page 52, first line, "in spite of a possible *removal*" should have read "in spite of a possible *renewal*."

DEATH.

Died at Uxbridge, Mass., July 19, 1888, Alonzo White Bennett, M.D., M.M.S.S., aged sixty-seven years.

BOOKS AND PAMPHLETS RECEIVED.

Biennial Report of the President of the Board of Health to the Legislature of the Hawaiian Kingdom. Session of 1888.

Fourteenth Annual Announcement of the Medical Department, University of Tennessee, Nashville Medical College. 1888.

Fifteenth Annual Report of the State Charities Aid Association to the State Board of Charities of the State of New York. December, 1887.

MASSACHUSETTS LUNACY LAWS.[1]

BY WALTER CHANNING, M.D.

The subject of this paper may not seem a very appropriate one to introduce at one of our meetings; but it is one which has been on my mind for several years, and I shall not feel satisfied until I have done everything in my power to at least bring it forward for discussion.

We can hardly hope in this world to find laws which will satisfy every one, as they owe their origin to human weaknesses, which require guidance and control, and the subjects of these defects do not care particularly to be guided and led, because they are incapable of managing themselves. None the less society must be maintained by rules and regulations which will be found to produce the greatest amount of good to the greatest number of persons.

More than any persons requiring laws for their protection are the insane, who especially appeal to our sympathy as a class, helpless through no voluntary transgression of social restraints, but through disease, the result of the age in which we all live and form a part. We are responsible for this disease, we ourselves may at any time succumb to it, and be thrown on the tender mercies of these very laws. Let us keep this idea then constantly in mind, and in considering the question, see if we should be willing to personally subject ourselves to the restraint and control liable to be forced upon us against our will, diseased and weakened though it may be.

As a starting-point, I wish to give it as my opinion, that our own State laws on lunacy, and those of many other States, are founded on a mistaken theory, as to the nature of insanity. This theory had its origin in the crude ideas of many years ago which regarded insanity as a loss of moral control, resulting in the free and unchecked play of the most vicious elements of human nature. The natural treatment of an insane person was in consequence similar to that which would be adapted to a person of criminal instincts, who had committed no overt act, but would be liable to commit such an act if not forcibly held in restraint. It was justifiable to confine and securely bind persons who were dangerous to society if at large. The safety of society was the first consideration. The suffering of the individual was of little importance, especially as it was due to his own wicked disposition.

During the present century, starting at its beginning and continuing to the present time, constant progress has been made, the details of which are familiar to you all, in the knowledge of insanity, and the treatment of the insane. One of the most striking tendencies in this progress has been toward the full recognition of insanity as a disease, in the pure sense of the word, and not as a moral weakness. And this simple and scientific doctrine of disease has revolutionized the intelligent treatment of insanity, and made, or is making institutions for the insane, *hospitals* instead of *prisons*.

That the public, though constantly growing more enlighted, do not yet fully comprehend the disease explanation of insanity is illustrated by the frequent details of brutal treatment of the insane at their own homes. The manner in which patients are carried to asylums is also another illustration of the same thing. Last year (1887) for instance, sixteen patients were carried to the State Asylum at Utica in restraint, which was immediately removed on admission. Sixteen patients was also admitted the same year into the State Asylum at Buffalo in restraint. Of these eleven wore hand-cuffs; three had in addition, shackles, one was brought in a muff, and one woman had her hands and feet tied with bandages. Almost any asylum could easily give deplorable details of the inhuman manner in which excited, but not dangerous patients have been treated before admission, and are brought to the institution.

But public opinion must be largely moulded by those having the direct care and treatment of the insane in their hands, and at the best can be expected to advance slowly and some distance behind its instructors.

The important and practical lesson we have been learning the last few years is — that the insane can be allowed a very large degree of liberty, and require little and probably no mechanical restraint while inmates of institutions. Unconsciously, almost, as to the influence at work to produce these results, we have rapidly increased the former and dimished the latter, until many of the tenets of ten years ago as to the asylum architecture, and management are already obsolete.

Ten years ago the rectilinear building, congregate treatment, and mechanical restraint were sacredly cherished, and strongly defended by nearly the entire body of American insane hospital authorities. Abroad they were striving after better things, and accomplishing them to some extent. In this country they were tabooed, or at least frowned upon and discountenanced.

Look at the transformation to-day! New York the head and front of conservatism in some directions in the care of the insane, not in all be it understood, is about to erect a new institution with twenty-two different buildings, many of them on the cottage plan, with congregate dining-rooms, diversified architecture, and every arrangement to carry the patient from a perfect hospital to a nearly ordinary dwelling-house.

The State Insane Asylum at Utica where for many years mechanical restraint was freely and openly applied and as openly advocated, has during the last year abolished restraint and given away the last "cribbed"!!

Certainly no more striking proofs of change and progress could be given than these.

During the ten years it will also be found that many small private institutions have been started, some of them being highly successful in every sense of the word. It is no accident that has given birth to these places. They come to fill a demand for greater freedom, more home-like surroundings, more privacy, more comfort than were formally to be found in large asylums. The improved condition of the insane required something more like the homes they had been accustomed to, and less institution-like, to fulfil the necessities of treatment.

With all these changes in the character of the insane and the consequent requirements of their treatment, it is well to examine our laws and see if the time has not arrived when they, too, may be revised with benefit. Are they not too narrow, too stringent, too inelastic? Is it necessary still to assume that the

[1] Read before the Boston Medico-Psychological Society, April 19, 1888.

managers of insane institutions are not to be trusted? Are committing physicians still to be held as corrupt and willing to aid in schemes to incarcerate insane persons in lunatic prisons? Are hospitals for the insane to be surrounded with so many safeguards, that the persons requiring their treatment must be frightened away? Is it not an outrage to make an insane hospital *difficult* of ingress? Should it not be made easy instead?

I cannot help feeling that the elaborate laws concerning insane hospitals help to keep alive the spirit of distrust at times more or less noticeable throughout the community. They constantly say to the public, "these institutions are dangerous places, they are full of temptations to lure the feeble, sick, and impoverished inside their gates, and when once within, to abuse and maltreat them."

It is always urged by the friends of these cast-iron laws, that the liberty of the person is sacred, and should only be controlled by law. This is true enough as long as the person is in his right mind, but once he loses his power of reason, he forfeits the right to use what he cannot be held to be responsible for. If he loses this controlling power by means of *disease*, no court can restore it to him. This, medical treatment alone can do. And medical knowledge only can determine when the power is lost, and when it is regained.

It is just here that the element of *trust* comes in. The sick and insane man must be absolutely *trusted* in the hands of the physician, and no court, or law must interfere to say where, or how he shall be treated, any more than if he has a fractured leg, or typhoid fever. The law may manage his property, and guard his interests, and keep any rights for him, or restore them to him, but his medical treatment it has no concern with.

We seek by our lunacy laws to do away with this element of trust, but after all they only divide the trust, or throw it into incompetent hands. Let us for a moment, for instance, consider the final order of commitment which sends the certified insane person to the asylum. This may be signed by "a judge of the supreme judicial court, or superior court, in any county where he may be, and a judge of a probate court, or of a police district, or municipal court." As we all know the majority of commitments are signed by judges of the probate court. "These judges shall see and examine the persons alleged to be insane, or state in their final order why it was not deemed necessary or advisable to do so."[2]

Now these judges often do not see the alleged insane persons; and it is not necessary for two reasons. (1) They can *trust* in the certifying physician, and (2) They know very little about insanity, and cannot be expected to judge what form of treatment the insane person may require.

The law should not have been optional, for it leaves a loop-hole open for the judge to shirk the responsibility, and further offers an opportunity for dishonest persons to so deceive the judge that he shall not deem a personal interview necessary. It is one of those laws that is more honored in its breach, than in its observance. As far as I can see there is nothing in this law which can prevent the possibility of a sane person being committed to an asylum, and the mistake would be a worse one if done with the approval of the judge, and harder to rectify.

[2] Sec. 34, Laws Massachusetts.

As a matter of fact I do not believe any respectable physician is guilty of conspiring to falsely restrain an insane person. It would be too dangerous, and risky, too easily found out, and apart from moral considerations, no man of ordinary sense would be tempted to do such a thing.

Consequently it is my opinion that as far as corrupt practice on the part of the physicians is concerned, the order of the judge could be dispensed with.

The procedure under the laws of New York for committing insane persons to insane institutions is more reasonable and practicable both from the point of view of the judge and the physician. These laws[3] specify that "no person shall be committed . . . except upon the certificate of two physicians, under oath, setting forth the insanity of such person. But no person shall be held in confinement in any such asylum for more than five days, unless within that time such certificate be approved by a judge, or justice of a Court of Records . . . and such judge, or justice *may* institute inquiry, and take proof as to any alleged lunacy before approving, or disapproving of such certificate."

It will be noticed that the function of the judge is here simply that of approval that the medical certificate is properly executed according to law. The responsibility of deciding as to the *mental condition* of the lunatic is not thrown upon him. But he has the authority to make a judicial investigation if for any reason he may think it necessary. And certainly no one would wish to take away this power from him, as his hands are the proper ones to place it in.

Contrast the Massachusetts law which places on the judge's shoulders the responsibility of saying "that the person committed is insane, and is a fit person for treatment in an insane asylum. And said judge shall see and examine the person said to be insane, or state in his final order the reason why it was not deemed necessary or advisable to do so."[4]

Even the laws of Pennsylvania of 1883 are much more reasonable in regard to commitments, than are the Massachusetts laws. The section of the laws on this subject is as follows: "No person shall be received as a patient for treatment, or for detention into any house, or place where more than one insane persons are detained for compensation without a certificate signed by at least two physicians resident in this Commonwealth, who have been actually in the practice of medicine for at least five years; both of whom shall certify that they have examined separately the person alleged to be insane, and after such examination had do verily believe that the person is insane, and that the disease is of a character, which in their opinion, requires that the person should be placed in a hospital, or other establishment where the insane are detained for care, or treatment, and that they are not nearly related by blood, or marriage to the person alleged to be insane, nor in any way connected as a medical attendant, or otherwise, with the hospital, or other establishment, in which it is proposed to place such person. The certificate above provided for shall have been made within one week of the examination of the patient, and within two weeks of the time of the admission of the patient, and shall be duly sworn to, or affirmed before a judge or magistrate of this Commonwealth, and the county where such person has been

[3] L. 1874, chap. 446, title 1, art. 1, sec. 1.
[4] Section 12.

examined who shall certify to the genuineness of the signature, and to the standing and good reports of the signer."

The next section of the Massachusetts law,[5] which provides for the physician's certificates is well enough as far as it goes, with one exception, and that is the absurd clause which specifies that neither of the certifying physicians shall be connected with any hospital, or other establishment for the treatment of the insane.

Nothing could be less necessary, or more unreasonable than this provision, and further than this, it works real injury to the lunatic, for he loses the services of asylum specialists who are certainly more competent to certify intelligently than most physicians as to his mental state.

The apparent animus of this law is to guard against the asylum physician certifying, and helping to commit a patient to an institution in which he may have an interest, but supposing he has an interest in one institution only, what possible reason can there be in preventing his signing certificates for other places? Both the English and New York and Pennsylvania laws adequately and properly cover this point. The laws of the latter State say:[6] "It shall not be lawful for any physician to certify to the insanity of any person for the purpose of committing him to an asylum of which the said physician is either the superintendent, proprietor and officer, or a regular attendant therein."

Just this should be the law. When carried further and made to include every physician connected with a lunatic asylum, it is unjustifiable from every point of view.

The New York laws contain a very good provision in regard to the physician's qualifications which might be incorporated into our own laws with advantage. This is — that his qualifications shall be certified to by a judge of any court of record. Such a provision as this is a guaranty that as far as ordinary requirements and reputation go, the certifying physician is competent. It strengthens the hands of the physician, and gives more value and weight to his certificate.

The sections of our laws, numbers 26 and 27, which relate to emergency certificates, or commitments, have never seemed to me entirely satisfactory, as they either put into motion a good deal of cumbersome machinery, or are not strictly adhered to. Their object is to bring the alleged insane person under treatment within the shortest possible time, but if literally adhered to, the attainment of this object is under some circumstances extremely difficult, if not impossible. In the first place the applicant must answer the numerous list of questions given in section 15; the physicians' certificates must be *separately made* and signed, and in addition the application must be signed by one of the selectmen of the town, or the mayor, or one of the aldermen of the city in which the person to be committed resides.

It takes time to answer the questions, and a portion of them might be easily omitted, still they can usually be answered and perhaps the time required may not be ill-spent. There is certainly no need that the physicians' certificates shall be separately made and signed. If a provision is made that both physicians have examined the patient personally, one certificate with both signatures is sufficient.

[5] Section 13.
[6] Section 2.

The most troublesome feature of all is that providing for the signing of the application. In each individual instance, of course, the official specified should be found, and he should first investigate the case before signing his name. It is often, however, no easy matter so find any of these persons, at night, in midsummer and at other odd times, out of business hours. If the law is observed to its letter, nearly, if not quite as much time will be required to make out the emergency commitment as the ordinary commitment. There is a little more red tape about the latter, but where it is regularly and systematically tied up every day, the difference is insignificant.

Then, too, the emergency commitment requires a bond to the amount of one hundred dollars, to be given by the party committing the insane person. I must say I see no reason for this section of the law. The bond is to be given to the treasurer of the asylum, or hospital, which would lead one to suppose that it was to secure payment for the board of the insane person for the five days allowed by the emergency law. But I can see no more reason why a bond providing for payment of board should be necessary in the emergency case, which is for five days only, and in the exceptional case, than in the ordinary case. If there is any other or better reason for this bond, why should it be given to the treasurer of the hospital? Is it a guaranty of good faith? If so, it is a very unusual proceeding to make money the basis of such a guaranty. The other provisions of the law should make such a guaranty unnecessary. We may further question who is going to give the bond in the case of the ordinary pauper. The law says the "person committing." Who *is* the person committing? An application is to be *signed*, but the maker is not mentioned. Is the physician? Has he any right to make both the application, and the certificates? It may be held that the signer is the applicant. The next question is, shall the signer, be he mayor, alderman, or selectman, give the bond? If he does this, additional time will be required to consider this question.

I know now that physicians often go on this bond, but it is placing an unnecessary burden on them, and one not intended by the law.

The next section to be considered is that relating to *voluntary commitments*, a recent and important addition to our laws. A similar law is now in force in Scotland, and the Commissioners in Lunacy say of it in their last report for 1886: "Forty-nine voluntary patients were admitted into asylums," (the total number of registered lunatics being 11,025). "We have for some years been able to state that nothing has occurred to indicate any difficulty or disadvantage traceable to this class of patients in asylums; and we continue to be of opinion that this is a useful provision of the law which permits persons who desire to place themselves under care in an asylum to do so in a way which is not attended with troublesome forms, but which, nevertheless, affords sufficient guarantee against abuse."

I am glad to see this testimony in favor of the Scotch law, though the number of voluntary commitments is small. I have not at hand the Scotch law and do not know whether it is essentially like our own.

Perhaps evidence from our own hospitals and asylums would be somewhat similar. But the whole number of voluntary commitments is small, which may mean that the institutions do not generally favor

them, or that few persons among the public understand, or care to avail themselves of the law.

We find from the Report of the Board of Lunacy and Charity, for 1887, that during the six years the voluntary commitment act has been in operation, only two hundred and sixty persons have availed themselves of it, and most of these have gone to the McLean Asylum. During these six years the whole number of commitments from the general community was eighty-five hundred, and the number of voluntary commitments was scarcely four per cent. of the whole number. During the year 1887 there was less than fifty voluntary commitments, thirty of these being to the McLean Asylum. The balance was scattered about among the public lunatic hospitals. At Danvers there were but three voluntary commitments in 1887, which seems a very small number out of so large a total number of admissions, four hundred and forty-six in all. The deduction from this fact might seem to be that among the poorer classes in the community there are none, or nearly none of those persons "whose mental condition is not such as to render it legal to grant a certificate of insanity." Otherwise how can we explain the large number of voluntary admissions at the McLean Asylum, twenty-nine persons out of a total of seventy-four persons?

There is undoubtedly another explanation, which is something like this: The ignorance of the lower classes is always an obstacle in the way of early treatment, and the poverty of the middle classes, or those persons a grade above the lower classes, prevents them from seeking those surroundings which would be agreeable to them while still retaining their reason. Both of these classes, when once unable to care for themselves, must be sent away to those institutions provided to take them at the lowest cost. It is no longer a voluntary question with them, or their friends, but rather a necessity, and this settles the question of commitment.

With the upper classes the question is the exact opposite. They can be influenced at an earlier period in their disease to seek treatment and they further have the requisite means to pay for surroundings in keeping with those at home, to which they are willing to go, and their friends are willing to send them, at an early period.

I suppose the provision laid down in section 28 of the law is, however, rarely adhered to as to whether the mental condition of the alleged insane person is "not such as to render it legal to grant a certificate of insanity." If the person is undoubtedly insane, then the institution has no legal right to admit him, no matter how willing he may be to voluntarily commit himself, but as far as my observation goes, the admission has usually turned on the latter point. We all know that many insane persons are quite able to sign voluntary agreements, but no such person can be admitted under the law. If the mental condition of the person is obvious, then of course a certificate can be made out, and he must be committed in the ordinary manner.

The voluntary law from its language, is intended for the *sane* and not for the *insane*, and should not be used to commit the latter. Of what use otherwise are complicated lunacy laws, if persons deprived of the natural use of their ordinary reasoning and will power can shut themselves up in insane asylums under the pressure usually of their friends and relatives? And further, supposing the voluntary patient becomes violently insane, what is his legal status then in the asylum? If he entered the institution of his own accord, in a semi-insane condition, he certainly passes when violently insane into a perfectly defenseless condition, and could under no circumstances more need any protection the law may grant than at such a time. Is he still to be regarded as a voluntary inmate, able to leave after three day's notice? This is manifestly absurd, and leads to the inevitable conclusion that if the voluntary patient admitted sane, becomes insane, he should be regularly committed.

Section 29 provides for immediate notice to the Board of Lunacy and Charity of the voluntary admissio ns, and the Board is required to immediately investigate such cases. What this investigation may be, I do not know, but it should be made at once by a medical man capable of judging of the various degrees of mental disease, and the Board of Lunacy and Charity should from time to time make a special examination of the voluntary cases. In my opinion there should be some legal provision whereby the person desiring to enter an insane asylum voluntarily, may so commit himself independently of the asylum authorities. For instance, one or two physicians should certify to his mental disease partial or developed, and to the asylum being an appropriate place for his treatment. This certificate then to be approved by a judge of probate, or some other official.

As the insane asylum is primarily, and strictly should be for the insane alone, the sane should be excluded, rather than invited to seek its treatment, but cases of partially-developed disease for the time practically insane, should gain easy admittance. The certificates of one or more physicians need only certify to the facts, and to the desirability of treatment. The approval of a judge would be the only bit of red tape, which could be easily managed, and the voluntary cases would then be placed on record and have some legal standing.

The small private institutions are at present discriminated *against* so far as the voluntary law is concerned. The law says (sec. 26), "The superintendent, or keeper of any lunatic hospital, . . . may receive into his custody, etc." It has been held by the Board of Lunacy and Charity that the small private institutions were not included in the meaning of this law. Such may, or may not be the correct interpretation of the law, the Board has, at any rate, the power to enforce this interpretation, and we now find that no small places receive voluntary cases.

As they, more than any other institutions are especially adapted to receive just such cases, there is manifest injustice somewhere. If they are not properly organized and managed, they should be brought up to the requisite standard. If the law is not full enough to take them in, it should be enlarged.

There are probably defects in both these directions in consequence of the possibility of which the Board ruled against them. The remedy is to include them clearly in the law admitting voluntary cases, and then to provide for adequate supervision. The latter is both necessary and just, as they have no trustees, are proprietary, and are growing steadily in number.

Another unnecessary provision in our law is section 30, which provides that "Any physician who wilfully conspires with any person unlawfully, or improperly to commit to any lunatic hospital, or asylum . . . any person who is not insane, shall be punished by fine, or

imprisonment at the discretion of the court." This section may have been suggested by the English law, 16 and 17 Victoria, chap. 96, sec. 13, which says, "Any physician, surgeon or apothecary, who shall sign any certificate, or do any other act (not declared to be a misdemeanor), contrary to any of the provisions herein contained, shall for every offence forfeit a sum not exceeding twenty pounds."

It must be remembered that the history of institutions for lunatics in England is entirely unlike that in this country. The English laws have been made from time to time to meet the special requirements of the circumstances, and often stringent laws were at the time necessary.

With us the case is different. Our lunatic asylums are well-managed. The public has confidence in them, and is satisfied with them. The small private asylums are strictly medical in character, and up to the present time have received few patients.

We do not require stringent laws to regulate admissions, but rather the doors of lunatic asylums should be easily opened to encourage early treatment. Neither do we require elaborate laws regulating the care and treatment of the patients while in the asylum. The mismanagement and abuse formerly somewhat prevalent in the English proprietary asylums are hardly possible in this country.

What we do need, however, is careful *medical* supervision of our whole system of provision for the insane. Every year this need becomes more apparent and urgent. A *medical* commissioner in lunacy, of ability and experience, is the person to whom this work should be confided. No other person, however competent, would in my opinion, be able to satisfactorily supervise the details of work, which must never be allowed to lose its medical character.

In Massachusetts the institutions for the insane are so compact that they can be easily visited, and the details of a practical system could be put into operation somewhat after the manner of New York. But here the result would be of a very different character; for while no one man can efficiently supervise the system of provision for the insane covering such an immense territory as in New York, here, one man could do it thoroughly.

The theory under which the New York commissioner in lunacy acts is excellent, but he is expected to do the work of three men, as a consequence of which his work loses very much in value, and the theory is never carried into practice as far as it should be.

I have merely outlined a few of the defects of our Massachusetts lunacy-laws. There are others which might be referred to perhaps rather as *blemishes* than *defects*. Our laws are in many ways excellent, and have worked pretty well, partly, I fear, because they have not been strictly followed. They would have been less satisfactory if followed to the letter. The time is coming, however, when some revision of these laws will be necessary, both for the purpose of improving on those in existence, and adding on others to cover the need of medical supervision, the wisdom of which I think no one will question.

The time for this revision may not have arrived as yet; but thinking that it is not far off, I have prepared this paper for the purpose of introducing a discussion on the three following points:

(1) Do our Massachusetts lunacy laws need revising?

(2) Has the time arrived for this revision?

(3) Shall a committee of this Society be appointed to prepare a revision of the existing laws, and a draft of new laws establishing a medical State commissioner in lunacy, to serve as the basis of future legislation?

KATALYTIC ACTION OF ELECTRICITY; ITS PRACTICAL VALUE IN RHEUMATIC AFFECTIONS.

BY G. L. WALTON, M.D.,
Clinical Instructor in Diseases of the Nervous System, Harvard University.

It has been long recognized that the effect of the electrical current on animal tissues comprises something more than the stimulation of nerves and muscles. Remak first called attention to the alteration produced in living tissues by the passage of the galvanic current, and applied the name "katalytic" to this function. Experiment has shown also that fluids may be made to pass into the body by means of special electrodes adapted to the purpose, a property of the electrical current which has been termed its "kataphoric" action. Whether the latter is an element in the production of the katalytic action, or whether vaso-motor changes, improved nutrition by stimulation of the trophic mechanism, increased tissue-metamorphosis, osmosis, or molecular changes, each or all, are important factors, cannot as yet be accurately determined; the conditions are too complicated for satisfactory experiment and analysis. The practical bearing of the question lies in the fact that therapeutic experiment has demonstrated beyond a doubt that such changes may be produced in the tissues as to cause improvement and even recovery in certain disorders not yielding to other treatment. Prominent among these disorders are subacute changes in or about the joints, of rheumatic origin.

Erb [1] quotes the observations of Remak, Rosenthal, Meyer, Cahen, Cheron, Weisflog, Benedikt, Onimus, Legros and Erdmann, as well as citing his own personal experience, to illustrate the practical benefit of electricity as a therapeutic agent in various forms of arthritis, including acute and chronic rheumatic and traumatic affections. It appears proved that exudation and pain may be made to disappear, and the normal mobility of the joints restored, in cases where other remedies have failed. Rosenthal and Bernhardt [2] allude to the effects of the galvanic current on rheumatic affections of muscles and joints, choosing the subacute and monarticular joint affections as the most promising objects of experiment. They recommend especially the galvanic current, considering faradism also valuable as a counter-irritant, as well as faradization of neighboring muscles. They state that even in acute rheumatism the faradic current and the wire brush have been found to lessen pain and shorten the disease, but throw doubt on its supplanting salicylic acid and other remedies. They allude to the passage of galvanism or faradism as promoting absorption of joint exudation and lessening the pathological processes in the neighborhood of the joint (fasciæ, tendons, periosteum and muscles). Beard and Rockwell [3]

[1] Handbuch der Elektrotherapie. Leipzig, 1882, p. 251.
[2] Elektrizitätslehre für Mediziner und Elektrotherapie. Berlin, 1884, p. 439.
[3] Practical Treatise on the Medical and Surgical uses of Electricity. New York, 1878, p. 541.

state that electricity has been employed with more or less success in rheumatism from the early periods of the history of electrotherapeutics, and add that this is the disorder against which (next to paralysis), the original experiments of electrotherapeuticians were most frequently directed. They lay stress on the importance of the *general* application of electricity, inasmuch as the disease is constitutional, and recommend general faradization quite as strongly as local application. They find subacute and acute cases far more amenable to treatment than chronic. For the local treatment galvanism and faradism are recommended alternately. The general application is said to increase the flow of urine, to cause generally more or less exhilaration, and to relieve pain; the local application relieves pain, reduces inflammation, and when effusion has taken place, causes absorption; the latter being affected by both currents, in some cases more powerfully by the galvanic. The caution is added that if the currents are used too strong or too long, the pain and inflammation may be increased. In the cases quoted by these authors, general faradization seems to have been the chief agent, although in one case the application was made with special reference to the diseased parts. In myalgia, or muscular rheumatism (characterized by pain on movement diffused through the muscles, and caused usually by exposure to cold and dampness), local faradization with the mild current either stabile or labile, usually causes relief in a short time. Stabile galvanism may relieve at once; severe applications may increase the pain. They add: "Of the large number of cases that we have treated, nearly all have been relieved by one, two, or more applications. A single application with a mild current, prolonged for one or more hours, may sometimes dissipate an attack of myalgia." In one of the two cases cited, general faradization was used in a case of several years' standing, cure resulting in three weeks. In another case, muscular rheumatism existing in the hips and limbs for a month, recovered in a fortnight under daily faradization of the affected parts. Duchenne[4] reports cases of muscular rheumatism, rheumatic paralysis, and rheumatic contracture, cured by the use of faradism.

Other authorities could be cited to confirm these observations, but enough have been mentioned to show that the subject is one which has attracted universal attention among electrotherapeuticians from the first. It seems, therefore, somewhat remarkable that the profession in general have made so little of this branch of electrotherapeutics, even while the application of electricity has been greatly in vogue for all forms of paralysis, for which it has for a long time been applied indiscriminately, sometimes in accordance with, but oftener in defiance of scientific principles. The experience of the writer has been most satisfactory in the treatment both of muscular and articular rheumatism; successful results have followed, almost without exception, in the cases where it has been tried; a careful selection of subjects having contributed largely to this result. Long standing, chronic cases, such as deforming arthritis, have not been operated upon, for in no such case has the prospect of recovery seemed sufficient to warrant the trial. Cases of acute rheumatism, again, have hardly seemed to me appropriate subjects for this form of treatment, in which opinion I coincide fully with Rosenthal and Bernhardt, quoted above. Indeed, far from electricity replacing internal remedies in the treatment of acute rheumatism, it is to be feared that more harm than good would be brought about by its use.

[4] De l'électrisation Localisés, p. 883.

The cases selected have been limited to subacute, monarticular rheumatism, to muscular rheumatism of not too long standing, and to allied conditions. In every case the electricity has been applied locally. I would not underrate the value of general faradization for cases of general debility resulting either from persistent rheumatism or from other causes. I do not, however, feel convinced that the root of the disease, as such, is directly attacked by general faradization as implied by Beard and Rockwell. My experience leads me to emphatically endorse the caution of Beard and Rockwell regarding excessive length and strength of application, especially in acute cases. A medical friend, suffering from subacute rheumatism, having found the faradic current extremely efficacious in reducing the swelling of the finger-joints, gave himself a sitting of forty-five minutes with a strong current, and produced thereby a decided accession of pain, stiffness and swelling. In one case of muscular rheumatism, again, quite acute, the galvanic current was given by my advice, and ten cells of the chloride of silver battery, applied ten minutes, aggravated the trouble so greatly as to cause its discontinuance. The exact amount of electricity received in the case cannot be accurately determined, since no galvanometer was used. The following will serve as illustrations of more favorable cases.

Case I. J. R., janitor, thirty years of age, treated in conjunction with Dr. W. J. Otis. Two months previous to the commencement of treatment, had rheumatic fever with pain and swelling, involving principally the right fingers and wrist, the right shoulder and ankle being also affected. The symptoms rapidly disappeared, excepting in the right wrist, where considerable pain, and marked swelling and stiffness persisted.

Examination shows the wrist red and swollen: it can be flexed fairly well, but neither extended nor adducted without great pain, and not to a great degree even with pain. He cannot double the fist, nor approach the thumb to the little finger: flexion of the fingers, both active and passive, is impossible, and spreading of the fingers is difficult. The grasp with the dynamometer is zero. Massage is painful. The muscles of the extensor group are wasted, — the right forearm measuring 9 inches, the left 10½ inches; the right wrist measuring 7½ inches, the left 7⅛ inches. The reaction of the extensor muscles, both to the galvanic and faradic currents, is decidedly lessened in degree, though not altered in quality (that is, no degeneration reaction). Lead-poisoning, poliomyelitis and neuritis were carefully eliminated.

Treatment. — A moderate galvanic current passed through the wrist and fingers (medium-sized electrodes of metal covered with chamois-leather); faradism and galvanism to the muscles. The electrodes were placed opposite each other, at different points about the wrist, and held quietly, so as to allow the current to pass directly through, the current being occasionally reversed. Each sitting lasted about twenty minutes, and was repeated daily.

Improvement was apparent after the first sitting. On the third day the patient could flex the fingers, and reach the last phalanx of the little finger with the

thumb: slight adduction of the wrist was possible, and the grasp was improved. At the end of the first week the dynamometer registered six: there was no pain on movement, little on massage. At the end of the second week the dynamometer registered ten; there was no pain on movement or massage; the fingers were easily spread, and the thumb could be approximated to the base of the little finger; adduction fair; extension possible to the straight line; swelling lessening, and forearm increasing in size. A splint was applied to assist extension. At the end of the third week the right forearm had increased from 9 to 9⅜ inches, and the right wrist had decreased from 7½ to 7¼ inches; the dynamometer registered fifteen. At the end of the fifth week no swelling was perceptible at the wrist; all movements of the wrist and fingers were free, excepting a very slight restriction in extension; the grasp was good, although the fist could not be clenched quite as firmly on the right as on the left. Treatment discontinued.

CASE II, kindly referred to me by Dr. J. R. Chadwick. A prominent lawyer, beyond middle age, a rather heavy man, had suffered during the previous winter from a severe attack of sciatica, which entirely disabled him, and required the use of opiates. This wore off, and by spring he was able to get about easily. Early in the summer the ankles began to show a tendency to swell, more especially the left. The trouble increased until it caused the patient considerable annoyance. The swelling was unaccompanied by noticeable pain or redness, but was increased by exercise, being particularly marked at night.

Treatment was commenced in the middle of October, no promise of benefit being held out. The faradic current (every other day) was first applied, and the result was so gratifying that this form of electricity was used throughout. The swelling could be seen to lessen, and the movements of the feet to become more free during each application. The return of the swelling between the applications became gradually less marked, and in two months and a half the ankle was virtually normal, and the treatment was discontinued. Recurrence of the trouble one month later caused the treatment to be recommenced, with similar result, two weeks proving sufficient for recovery. During the two years succeeding there have been occasional intervals of moderate swelling, accompanied by slight pain and stiffness, not sufficiently marked to require treatment. There has been, also, one attack of sciatica.

I have treated a number of cases of muscular rheumatism, notably of the neck and back, with results coinciding with those of Beard and Rockwell and other writers. No case, however, offers sufficiently marked or unusual characteristics to justify especial mention. The rapidity with which pain and stiffness sometimes disappear under the treatment certainly warrants the assumption that the current produces some definite change in the tissues, and acts as something more than a stimulant to nerves and muscles. It seems not improbable that here, too, we have to do with the absorption of a moderate degree of exudation. Cases of the ordinary form of stiff neck from exposure to cold have shown marked results from the use of galvanism to the affected side and faradism to the opposing muscles.

Swelling of the ankles like that seen in the second case quoted above is not an uncommon symptom in corpulent people, without cardiac or renal troubles, and even without the rheumatic tendency evident in his case. In several cases of this nature, as well as in the troublesome cases of pain in the heels and soles of the feet caused by overuse, and which can hardly be classed either under rheumatism or neuritis, but which tax severely the patience of both physician and sufferer, I have been surprised at the degree of benefit obtained from the use of electricity, and in place of suggesting it as a last resort have become encouraged to recommend it in many of these cases with considerable confidence. In this class of cases the faradic seems fully as efficacious as the galvanic current, the explanation of which it would be premature to attempt in the present unsettled state of our knowledge regarding the effect of either current upon the organism. The thought would suggest itself, however, that counter-irritation and the modification of the superficial circulation play a great part in the cures effected by faradism, in contradistinction to the katalytic action of galvanism. Further investigation is desirable to aid in the classification of cases, and to permit more definite indications for the choice of currents, the object of this paper being rather to emphasize the practical advantages to be gained by this form of treatment than to discuss the theory of its action.

REPORT ON FOOD AND DRUGS, THEIR SOPHISTICATION AND ANALYSES.

BY B. F. DAVENPORT, M.D.

FRANCO-SWISS MILK FOOD.[1]

COMPOSITION.

Water	4.16 per cent.
Fats	1.94 "
Milk sugar and grape sugar	9.70 "
Cane sugar	84.62 "
Starch	33.02 "
Soluble carbo-hydrates	46.85 "
Ash	1.43 "

Its agreeable flavor resembling cake is due to the milk solids, and the mode of preparing the cracker before powdering.

LŒFLUND'S CREAM EMULSION.[1]

COMPOSITION.

Water	24.32 per cent.
Fats	15.32 "
Soluble albuminoids	2.24 "
Insoluble "	4.99 "
Maltose and lactose	43.16 "
Dextrine	6.27 "
Ash	2.60 "

Similar in appearance, smell and taste to butter-taffy, the advertised analysis agrees reasonably well with the above, which is unusual for any proprietary food. But what is more remarkable it has over twice as much butter fat as is claimed for it, while usually such preparations contain less than a fair whole milk would naturally yield. It does not dissolve readily in water, white curds separating and coming to the top. It is much too sweet to resemble cow's milk. Such an excess of saccharine matter is highly objectionable.

WELLS AND RICHARDSON'S LACTATED FOOD.[1]

The name of this food conveys a false impression for it does not contain any milk.

The claim that it contains fifteen per cent. of malt diastase, retaining its full activity, is not sustained by the analysis, where no diastasic action upon the over

[1] Report of N. J. State Dairy Commissioners for 1887.

one-third part starch was found when the food was brought into solution. In the presence of so large an excess of alkali no such action is to be expected. Its albuminoids are derived from the gluten, etc., of the cereal, and not from milk.

COMPOSITION.

	As advertised.	As found.
Water	....	7.76 per ct.
Fat	....	1.64 "
Milk-sugar	25.00 per ct.	29.65 "
Malto-diastase	15.00 "	.... "
Soluble carbo-hydrates	41.67 "	39.00 "
Starch	.... "	36.43 "
Gluten and soluble albuminoids	16.35 "	.... "
Albuminoids	.... "	11.85 "
Potassium bicarbonate	1.25 "	.... "
Phosphates	0.25 "	.... "
Sodium chloride and other salts	0.48 "	.... "
Ash	.... "	2.61 "
	100.00	

MALTED MILK.[2]

COMPOSITION.

Water	2.18 per cent.
Fat	5.30 "
Albuminoid	16.88 "
Soluble carbo-hydrates	66.99 "
Starch	5.57 "
Malt-sugar and milk-sugar	50.40 "
Ash	3.13 "

This food differs from Nestle's and others like it in that most of the starch has been converted by malt diastase into maltose. The malt extract in the food as sold, has no diastatic activity. The claim that the caseine has been predigested by the diastase, that is converted into a soluble form, is not found to be true. The caseine in the "Malted Milk," is present with its properties no more changed than thay are in Nestle's, the Anglo-Swiss, Carnrick's Soluble Food, or other similar milk foods, prepared by evaporating down baked wheat powder with condensed milk. In all of these it is left behind as separate, hard, unchanged particles of caseine.

REED AND CARNRICK'S LIQUID PEPTONOIDS.[2]

COMPOSITION.

Water	64.694 per cent.
Alcohol	15.136 "
Albuminoids	2.021 "
Fat	0.031 "
Carbo-hydrates, mostly sugars	17.666 "
Ash	0.350 "

This claims to be "concentrated beef and milk with gluten perfectly digested." It is a strongly alcoholic liquid of a light yellow color, with an alcoholic burning taste, and with a smell similar to that of many preparations of hair oil. It appears that the insidious introduction into the bed-room of an invalid, of a preparation claiming, as this does, to be of a highly nutritious character, and yet which is principally composed of alcohol, is a criminal act. There is nothing on the label to make him suppose that he is drinking something which is almost entirely sweetened alcohol. In communities where the sale of spirituous liquor is prohibited, this liquid peptonoids could supply in secret, a morning dram to every toper, under the guise of medicine.

RHUBARB.[3]

Chinese rhubarb may, according to Dr. Boni, be distinguished from the European by the amount of lime occurring in the ash. The former yields 20 to 25% ash, while the latter 8 to 9%. This difference being due to the amounts of calcium oxalate which they contained.

[3] Pharm. Post, Jan. 22, p. 51.

UNFERMENTED WINES.[4]

Mr. Millard reports on his examination of unfermented wines sold for sacramental purposes as free from alcohol, that where he found the alcohol absent, some preservative, such as salicylic acid was present. None of these were genuine, but rather merely acidulated and colored syrups. Cochineal or some other coloring was present in all.

PEPPER.[5]

Of late years, grain of paradise has become a frequent form of adulteration in powdered pepper. This may be detected not only with the aid of the microscope, but also from the presence of tannin which is not to be found in the genuine pepper. The powder treated with a mixture of alcohol and ether yields the tannin, which is shown by its reaction with tincture chloride of iron.

SWEET WINES.[6]

Considering the extensive use of such for medicinal purposes, the results of the analysis of American samples by the United States Agricultural Department, are of interest to physicians. They were, that but little of the pure juice of the grape entered into their composition, but that they were chiefly composed of alcohol, sugar and water, and partook more of the nature of a liquor than of a natural wine. The samples were of California, Sherry, Port, Burgundy, Muscatel and Angelica.

COGNAC PRODUCTION AND TRADE OF FRANCE.[7]

According to "Weinlaube," France yearly exports about 300,000 hectolitres of alcohol, while it imports 200,000 to 330,000. There is distilled from wine about 20,000 to 25,000 hectolitres of cognac, and about 6,000 more is imported, making altogether 26,000 to 31,000. There is, however, 150,000 to 160,000 hectolitres of so-called cognac exported annually, over 100,000, to England alone. One can judge from these figures what an immense quantity of artificial brandy is exported annually from France under the name of cognac.

PRIZE FOR THE DETECTION OF ADULTERATION.[8]

The Minister of Commerce in France has informed the Academy of Science that he is authorized to offer a prize of 50,000 francs to any one for the discovery of a simple and useful instrument for the detection of adulterations in wine and spirits.

CHAMPAGNE ADULTERATIONS.[9]

The perfection of adulteration is shown in the following circular sent out by a German wine dealer. "Our very large trade in champagne, enables us to offer you our cheap quality of champagne at 15,60 francs per dozen, inclusive of packing and shipping by way of Rotterdam or Antwerp. We wish to call your attention that we leave to you the selection of any labeling you desire, and beg that you allow us to send you a sample"— to leave thus to the purchaser the selection of the label, is to attain to the inimitable.

THE NATIONAL FORMULARY.

A collection of unofficinal preparations issued by authority of the American Pharmaceutical Association, 1888. This work is intended to include the more important of the large number of medicinal preparations which are more or less frequently prescribed by physicians, or demanded by the public, but which are not recognized in the United States Pharmacopœia, either because they were not deemed by the revisers to be of sufficient importance to be included in this official work or because they originated subsequently to the appearance of that work, or for other reasons. Owing to the absence of an authoritative standard, many of these unofficial preparations have been, and are being made after different formulæ, and in varying strength, so that pharmacists, particularly in the larger cities, are compelled to procure and keep on hand a variety of brands of what is intended to be one and the same preparation, to satisfy the demands of their patrons, professional or otherwise. In compiling the work, the needs of all sections of our country have been consulted. The list even includes a small number of formulæ in imitation of some of the popular nostrums of the present day, but constructed on rational principles for uniform composition and reliable effect, rather than for mere external appearance and taste. It is hoped that these will be used as directed to be used in place of the proprietary articles, the composition of which is generally kept secret.

As the mission the work is to fulfil can only be properly accomplished by the coöperation of the physicians, it is of the greatest importance that they make themselves acquainted with its object and contents, and that then they will consent to accept the preparations made in accordance with the formulæ contained in it, instead of designating any special maker's product.

The list of formulæ given in the work numbers 435, and includes 86 elixirs, 54 extracts, 41 liquors, 19 mixtures, 21 pills, 35 syrups, 33 tinctures, and 12 wines, besides the many lesser groups, and single members. In constructing the formulæ of the compound preparations, it has been endeavored to make them as independent from each other as possible, so that only a comparative small number of what may be called basic preparations are needed. If these, numbering about a dozen, are kept in stock by the apothecary in reasonable quantities, most of the compound preparations contained in the formulary may be prepared in a short time.

Clinical Memorandum.

HALLUCINATIONS OF HEARING.

BY J. ALBAN KITE, M.D., NANTUCKET, MASS.

A CASE recently came under my care, presenting hallucinations so peculiar as to warrant their being recorded. Mr. E., the subject, is over eighty years of age, and, with the exception of deafness has retained his faculties to a remarkable extent (deafness $\frac{1}{4\,0}$). Until the last few years he has lead an active public life. Has been temperate in all things save mental activity. A few days prior to my seeing him, he was one evening startled by a loud rapping on the window. He arose to ascertain the cause, when the sound was repeated on the opposite window, and followed by a shrill, derisive laugh. His wife, on being questioned, assured him there had been no noise. On returning, the same performance was repeated, save that there were two actors, a deep bass voice having come upon the scene, and a lively discussion was carried on between the two. The fourth night two female characters, or rather voices, presented themselves. The various events of the day were discussed in which all seemed to take a lively interest; but what seemed strange, their conversation was flavored with such laxity of speech, that Mr. E., although assured the condition was purely subjective, felt very uncomfortable with his wife sitting beside him.

These debates lasted for several evenings, and interested Mr. E. not a little. About 9 P. M., they adjourned, and did not again appear until the next evening, when reinforced by other members of the same troupe, they announced their presence by singing "Home, Sweet Home," without an error. This was followed by several solos; and the concert was kept up until after midnight. The number of these little creatures of his imagination increased from day to day as did the variety of their antics. They visited him in daylight; followed him in his walks; called to him from doorsteps, windows, and from behind trees.

Mr. E. never saw these creatures, but knew each by his or her voice. Those who first appeared never failed to pay him a visit during the day. Not one, however, assumed the voice of a friend. Under what, I trust, was appropriate treatment, although the number of voices remained the same, they had less and less to say, and more time elapsed between the visits, until I think the sixth day of treatment, all met in the evening, and after a quiet and peaceable gathering, dispersed, their exit being accompanied by a drum-corps: the latter, in Mr. E.'s own words, "seemed to beat a retreat."

Three weeks have elapsed with no return.

Mr. E. is perfectly sane. Has, so far as I have ascertained, no organic disease, save a slight cardiac valvular insufficiency, and the deafness which is due to lesions in both internal ears. He is in the best of spirits, but occasionally suffers from epistaxis, and, at night finds his ankle slightly swollen. Whether these hallucinations are the resultant of abnormal cerebral circulation and of irritation of already diseased aural ganglia or sensory nerves, I am ignorant. The treatment was with the bromides. Mr. E. has told me the substance if not the exact words, of conversations he has had with Daniel Webster, and can give last week's stock quotations as accurately as any financier. His opinion is often asked on various subjects, and results have shown his good judgment. I know of no one whose calm reasonableness is more to be depended upon, nor have I seen this latter condition departed from.

Reports of Societies.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

PHILIP COOMBS KNAPP, M.D., SECRETARY.

APRIL 19, 1888. DR. C. F. FOLSOM in the chair.

DR. WALTER CHANNING read a paper

MASSACHUSETTS LUNACY LAWS.[1]

DR. GEORGE F. JELLY said that he saw as much of the workings of the present lunacy laws as any mem-

[1] See page 97 of the Journal.

ber of the society, and he admitted that the laws had their defects. Commitment by the judge was less objectionable than if the judge had to see every case. He thought that that provision of the law protected the physician and the asylum superintendent, and that it was better that the judge should have the right to use his own discretion in the matter of seeing the patient, as thus there was less likelihood of abuse. Outside of Boston the judge sees most of the cases, but in Boston he sees only one-third to one-half. In some ways the New York laws are better, but while this provision is discretionary there is no special objection to it. The emergency law was probably intended to apply to those cases where no judge could be found, and it is a question whether it is legal to commit patients under it when the judge is accessible. He regarded the bond as a penalty, to be forfeited if the five-days' provision was not complied with.

DR. CHANNING said that the wording of the law was obscure on this point.

DR. JELLY said that in emergency commitments he signed the bond himself, regarding it as a penalty, and he thought that the physician could sign it. The clause requiring the signature of the mayor, alderman, or selectman, to an emergency application was too severe, but it was evaded in Boston by giving the Board of Public Institutions power to sign it by their clerk, who signed blank applications ahead for emergency use. These were accepted as legal by the Board of Lunacy and Charity. He thought that in ordinary commitments some judicial approval should be required, but there was no great danger of harm. It was unjust that no man connected with an asylum could sign. The reason why the public asylums have so few voluntary patients was not because patients refused to go on that basis, but because, in pauper cases, the towns objected to paying for board unless the patients were legally committed. He did not use to think that a lunacy commission was necessary, but he had now come to regard it as very important; a commissioner would revise the laws and report as to the necessity for changes.

DR. GEORGE T. TUTTLE said that he had supposed that the law intended that the judge should see every case, but that discretion was allowed in case it were likely to be injurious to the patient to have the judge see him. The judges who commit the fewest patients hold most strictly to the law. As papers from physicians out of the State are worthless, a number of the patients at the McLean Asylum have to be recommitted after they are brought there, so the judge holds court at the Asylum. If a patient is once there, however, the judge never has any scruples about committing him. The judge is very strict about not permitting any employee of the asylum to sign the application in such cases, but the signature of a saloon-keeper in Somerville will be accepted without question. He cited several absurd and questionable methods in which the emergency law was stretched in particular cases. He felt a security in commitment by a judge, and he regarded it as a protection to the asylum, especially in the case of a private asylum like the McLean. He liked the idea of regarding an asylum as a hospital and not as a prison. He agreed with Dr. Channing in regard to voluntary patients. They got many voluntary patients at Somerville, but only by a most liberal interpretation of the law. Many of these cases could be legally committed, so that their admission on a voluntary basis is illegal. Before the patient signs the request, Dr. Tuttle always explains to him the workings of the law, pointing out that the three-days' notice is merely to give time for a legal commitment, so that, if he gives notice of a desire to leave before it is advisable, he will be legally committed and be obliged to stay. If the patient knows this it often settles the matter, and the subject of leaving is never broached. Patients who know that an attack of acute mania is impending often came in as voluntary patients, to be cared for during their attack, which is also illegal. The Board of Lunacy and Charity are notified when a voluntary patient is received, but they do not investigate for some time. They may read the statement sent with the notice, but they never make any medical investigation. The voluntary basis is a good one for the patient, but the letter of the law is not strictly followed.

DR. J. H. DENNY commended the appointment of a lunacy commission most heartily, especially with reference to the importance of its having the responsibility devolved upon it, of making the initial inquiries and determining what should be done, in cases reported to it, where no one is willing, or in position to take the requisite steps. In this way the numerous homicides due to insanity might be checked, in all probability, as to frequency, if some central authority should assume the responsibility that individuals shrink from in making due inquiry and taking prompt action.

DR. T. W. FISHER said that the laws in the different States varied greatly, from a jury trial in every case in Illinois to the unsworn certificate of two physicians in Rhode Island. He gave an instance of the laxity of laws in the latter State, in a case which occurred in his own practice. The Massachusetts laws were better, but still they were faulty, and were more severe than the English laws in forbidding asylum superintendents to sign certificates. He thought that the judge should decide in every case of commitment, but it was too much to ask him to see every case. The emergency law as modified works well, but it is little used except in Boston and at the Boston Lunatic Hospital. It should be retained with modifications. The bond and extra certificate are needless, and the mayor and alderman clause is a farce, for blank signed applications are always kept on file. The voluntary law as practiced is a good thing, and beneficial for the patient, but, if strictly construed, the asylums could hardly take a case under it. Poor patients are often committed because if they went as voluntary patients, the physician would get no fee. The Board of Lunacy and Charity are sticklers for the letter of the law, but if the papers are correct they take no further interest and they never make any proper medical inquiry into the condition of the patient. It was none too soon to discuss these laws, and he believed fully in the necessity of having a commissioner in insanity.

DR. J. B. AYER liked the present method of commitment, but the law could not expect the judge to see every case; still it was well for him to do so if the physician were unknown. It was wise to require three years' practice, although it was unfair in some few cases.

DR. H. R. STEDMAN thought that the paper threw light on the flagrant deficiencies of the laws, but there were many minor defects. One was the narrow limit allowed for a patient's visit at home. It would be wise, if the physician saw the patient in the meantime, to

permit the patient to be returned to the asylum at any time within a year without a new commitment. Thus the patient could have the advantages of home life for a longer period, and would be spared the expense of a new commitment. The boarding-out laws were also defective. All hinged, however, upon the lack of a medical commissioner.

Dr. W. M. Knowlton thought it time to discuss the laws, although the Massachusetts laws are better than those of Connecticut, where the judge appoints only one man to examine the patient and sign the certificate.

Dr. P. C. Knapp believed fully in a revision of the laws and of the State and city boards. He had had occasion early in the winter to criticise the provisions of one of the recent enactments, but the only result was to call out a discourteous and irrelevant answer from an employee of the Board of Lunacy and Charity. He remembered that when he first committed a patient, although he was unknown to the judge, the commitment was made in the usual manner and the judge evinced no desire to see the patient. He saw no advantage and felt no relief from responsibility in a commitment by a judge. When he advised removal to an asylum he felt morally if not legally responsible for it, and the signature of a man who had never seen the patient and who knew nothing at all about insanity could do little to relieve that responsibility. In his brief asylum experience his method of informing the Board of Lunacy and Charity of the reception of a voluntary patient was by the bare formula, "A. B. has been admitted this day as a voluntary patient," without any statement as to the patient's condition. This was apparently accepted by the board, and no medical investigation was ever made. He believed fully in a commissioner or a board of commissioners in lunacy, or at least, that one or more ailenists should be placed upon the present board. The present state of things — a State Board of Lunacy and Charity, without a single man on it or connected with it who was an expert alienist — was absurd and disgraceful.

Dr. Fisher said that the judge is really responsible for the commitment, and he is the only person connected with the commitment who cannot be sued for infringement of the law.

Dr. Jelly, in answer to Dr. Ayer, said that practically no one was ever sued in this State, but the physician might be sued for malpractice.

Dr. C. F. Folsom said that laws were not the rules which were best for the community, but what the community demanded, and this was true of the lunacy laws. There was even now in the community a distrust of insane asylums. The clause forbidding asylum superintendents to sign certificates, was objected to at the hearing, but it was carried almost unanimously in the legislative committee. The laws can be criticised, but he knew of no respect in which by stretching them, they worked badly. The judge's share in the commitment he thought was a protection. If an attempt is made to revise the laws, may it not do harm by causing the passage of still more stringent laws? The voluntary law was of later origin, and was not passed as it was originally drawn. It included any one whether insane or not, but this provision was objected to and was stricken out. He doubted whether we could get the laws changed without getting more restrictions added. A lunacy commission was very desirable, but it was impracticable, for the whole Board of Lunacy and Charity and the State officials objected; furthermore, if it were established, it would not be possible to get provision for over $2,500 a year for the commissioner's salary, which was not enough to get a suitable man. In answer to Dr. Fisher he said that, for political reasons chiefly, very strong objections had been made to appointing an expert in insanity on the present Board of Lunacy and Charity.

Dr. Channing, in answer to Dr. Folsom's criticism, said that he was of the opinion that there were serious defects in our laws, as had been generally testified to by those present, and he did not feel that because it might be difficult to change the laws on account of public opinion we should give up trying to improve them. No reform came without effort. He therefore moved that a committee be appointed to consider the advisability of preparing a revision of the existing laws, and of drawing up new laws establishing a commissioner in lunacy, to serve as a basis for future legislation.

This motion was carried and the following committee was appointed: Dr. T. W. Fisher, chairman, Dr. Walter Channing, Dr. George F. Jelly, Dr. C. F. Folsom, Dr. P. C. Knapp.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

F. B. HARRINGTON, M.D., SECRETARY.

March 26, 1888, Dr. C. F. Folsom, President *pro. tem.*

Dr. J. J. Putnam showed a case of

PERIPHERAL PARALYSIS FOLLOWING THE USE OF THE RUBBER TOURNIQUET.

He said: I asked this patient to come around principally because he exhibits in quite a marked way an interesting electrical reaction. It is not anything new to those who are accustomed to making electrical examinations, but it is rarely seen so well. He is one of two patients that I have seen within a comparatively short time, where a paralysis of considerable severity of the nerves of the arm has been caused by a rubber tourniquet; although the tourniquet was applied with every care and with great precaution. He is a patient of Dr. Porter, who, in operating on his hand, had occasion to use this apparatus. He had particularly in mind this accident, which had happened to another patient, and took especial care that it should not happen in this case. The injurious compression of nerves by a tourniquet is of course not unknown. It occurs from time to time, but as a matter of fact, I have rarely happened to see it with the old-fashioned tourniquet.

The point for which I asked the patient to come down is this: The tourniquet was applied at about the middle of the upper arm, and as a consequence he has complete paralysis of all the muscles below that point. When I say he has, I mean he had two or three days ago. For both these patients' improvement was so rapid that I will have to ask you to take on my authority the symptoms which they ought to show. He can slightly move the thumb, and very slightly the ends of the fingers. But he is practically paralyzed. In spite of this, the sensation is preserved over the

skin except to a very limited degree in the parts supplied by the radial nerve along the radial border of the index finger. Otherwise he is well. The nutrition of the muscles and nerves is also very well preserved. The muscles of the thumb show to a very slight degree the familiar degenerative reaction, indicating that the degenerative process has travelled down the nerve-fibre to the muscle, and that the latter has become the seat of a subacute inflammation.

The flexor muscles, however, do not show that, and they feel tolerably firm; so that a portion of the influences which are necessary for the life of the nerve are still permitted to travel through the injured portion. On the other hand, the voluntary impulse is not able to make its way through the part. Not only that, but the electrical stimulation is not able to make its way through. This is shown strikingly, and it is not often that one has an opportunity to examine so easily an arm in this condition. I will put the electrode in the right hand, and with the other follow up the course of the median nerve. The muscles contract until the point of injury is reached, and at that point and above it they fail to respond. At the point where the injury occurred the reaction ceases entirely.

I think the fact that sensation can travel through this injured part, and that the nerve can carry the influences for the preservation of the muscle, suggests some interesting speculations. It has seemed to me that it is perhaps a question of degree of impression, and that a very strong voluntary impulse could get through this part. A case occurred to me a few years ago which I think lends a certain support to that view. The patient had got his arm injured by sleeping on it, and had been treated a long time without gain. He belonged to a fire company, and at the time of the great fire in 1872, went out to serve with the engine, using all his force without thinking about it, and the result was that from that moment his arm began to improve, and recovered rapidly. It has occurred to me that it might be a good policy to advise patients to make strong efforts within certain limits, in the treatment of such paralyses.

CORTICAL APHASIA.

The other patient is one whose main symptom has to a great extent passed away. He is the subject of aphasia, and at the time when I first saw him, which was two or three weeks ago, it was a sensory aphasia to a considerable degree. At that time he spoke but very few words, but those he used correctly, but he did not understand what was said. When I asked him to shut his eyes or show his tongue, he did not do it. Now he understands almost everything. The case is complicated by the fact that the patient is a foreigner, and speaks only broken English, still, he used to talk with his fellow-workmen with ease, and must understand a good deal. He can read English, and speak English with comparative facility. He says that two weeks before New Years, while he was working, he had a sensation of a peculiar kind in the finger and thumb of the left hand, a kind of pricking sensation. This travelled like a sort of aura up the arm, and reached the face and went down the leg. It followed the regular course of the auræ in certain epileptic cases. This happened four or five times. Then the same thing occurred in the right arm, and then he lost his speech. There was a slight degree of right hemiplegia. Even at the present time the lines upon the right side of the face are relatively obliterated. When he talks a very slight degree of facial paralysis is seen. The hemiplegia is now gone. He can walk about as well as ever.

He shows also a peculiar change in vision of the right eye. I wanted to discover whether he had any hemianopsia, and so I tried a method which was suggested to me by Dr. Gowers in London, and that was to see whether he would wink when the hand was moved before the eye one side, and not when moved in the field of the other side. I thought I found that he had hemianopsia, but Dr. Wadsworth examined him and found that the whole right eye was more or less insensitive. He had a sort of crossed amblyopia, and that I think still persists to a certain degree. The interesting thing is that although the sensory aphasias are by no means uncommon, forming a part of almost any aphasia, still sensory aphasia to the extent which this patient shows, I think is uncommon when combined with a motor aphasia, and yet not associated with more paralysis than in this case.

Here is another patient, who, a few days ago, presented a marked facial paralysis, which is undoubtedly cortical. It seems that this came on in the night. She felt a chill and pain in the right arm. Then this paralysis of the face came on. She could not at first speak a word. In a few hours she spoke a few words, and then she gradually improved, and is still improving. When I saw her first the lower facial muscles were entirely paralyzed on this side. Even now the masseter muscles contract with very different degrees of force. The left hand is not paralyzed, although she drops very heavy objects.

What she evidently had was the blockage of a little vessel not going to the aphasic region, but supplying, probably, the lower end of the ascending convolutions, where the ordinary motions of the mouth are represented. In the beginning, either from the effect of shock upon the neighboring parts, or œdema, or because the circulation in them, too, was in a measure impaired, there was first aphasia, which faded away, and the symptoms are now reduced to the facial paralysis; and even that is now fading away by reason of the re-establishment of the circulation on account of the anastomoses in the pia mater.

DR. E. H. BRADFORD showed by card a specimen of

OSTEO-CHONDRO-SARCOMA OF THE LEG,

which he had removed from a young man twenty years of age. The tumor had existed for three years, and had grown to immense size. Dr. Whitney, who examined the specimen, had stated that it was of periosteal growth.

DR. JOHN HOMANS said: It reminds me of a case I had of the thigh a year ago, where I amputated. The young man did well for about four months, then he had a recurrence inside the pelvis.

DR. BRADFORD: I had a similar experience in an amputation of the hip for a sarcoma of the thigh. It was well for two months and then came back again. The disease in the specimen shown is below the knee and I amputated above the knee. I am in hopes that he will get on without recurrence. There is no enlargement of the glands.

(To be continued.)

— Talc has been found by Paris physicians effective in infantile diarrhœa, in doses of 20 to 30 grammes daily, in milk.

AMERICAN OPHTHALMOLOGICAL SOCIETY.[1]

EVENING SESSION.

HYSTERICAL BLINDNESS IN THE MALE, WITH A REPORT OF THREE CASES,

by DR WILLIAM OLIVER MOORE, New York.

The average proportion of cases of hysteria in the male to hysteria in the female is one to fifteen.

CASE I. Male, aged twenty-five, farmer; family history good. During past two years had suffered with nervous symptoms. Did not smoke or drink. In June, 1886, complained of failing vision in left eye. When seen June 16th, according to patient's statement vision in left eye = 0; in right eye normal. Ophthalmoscope showed normal fundus except a slight patch of opaque nerve-fibre near the papilla. Testing with prism and candle gave double vision as did pressure on one eye-ball. The patient was informed that treatment by electricity would cure him in a few days. A severe faradic current was applied, causing the patient to jump from his chair exclaiming that there already was improvement. In ten days $V = \frac{20}{xx}$ emmetropic.

CASE II. Male, aged twenty-two, student and farmer, fine looking; history of insanity in the family. Eighteen months previous to coming under observation atropia had been instilled by a physician to determine whether or not glasses were required. He thought from the effect of the atropine that he was going blind. He then put on smoked glasses, subsequently bandages and kept in a dark room. He would not open the lids and declared that he was blind. For ten months he kept in a dark room with covering over the eyes. On examination the lids were closed but not by spasm; the cornæ clear. V = 0. Ophthalmoscopic examination under ether, normal fundus. Hysterical blindness was diagnosed, and a favorable prognosis given. Cantholastis was then performed. Coming from the ether the patient opened his eyes and evidently saw clearly. He was told that the cause of the disease had been discovered and that he would be well in a few days. In two days he was walking around without glasses. Has remained well since.

CASE III. Boy, aged fifteen. Developed blindness in right eye after a disappointment at school. Normal appearance of eyes. Tests with prisms and colored glasses showed that vision was present. Ether was administered and patient assured that he would be well, and under electricity recovery was rapid.

DESCRIPTION OF A SERIES OF TESTS FOR THE DETECTION AND DETERMINATION OF SUB-NORMAL COLOR-PERCEPTION, (COLOR-BLINDNESS), DESIGNED FOR USE IN RAILWAY SERVICE,

by DR. CHARLES A. OLIVER, Philadelphia.

It is a well-known fact, both from theoretical and practical stand-points, that many "color-blinds," especially those of medium grades, have the power of differentiation even by day-light, of the most difficult colors when placed at ordinary metre distance of wool selection employed in the detection and determination of color-blindness. The writer has been induced through a hope to overcome the dangers that might arise from this power in situations such as railways, marine and naval service, where the safety of lives and the protection of property is oft-times solely dependent upon proper recognition of color at great distances and frequently through the intervention of more or less translucent media, to combine two modifications of his method of color selection to a simplified plan of the former procedure by which the candidate is placed in the actual position of after-work and under exactly similar circumstances as during employment. The method is divided into three parts.

First, the selection and registry of a definite number of loose wools from twenty-three pure and confusion match skeins thrown upon a dead black surface at one metre distance.

Second, the selection and registry of the same number of similar reflected colors under various intensities of diffuse day-light stimulus, placed at distances requisite for safety.

Third, the selection and registry of transmitted colors under various intensities of artificial light stimulus placed at distances requisite for safety.

In addition to the advantages shown to refer to the first test alone, this method has the following additional ones:

(1) Much faster in time than any other method. (2) The selection of loose wools at a distance. (3) No necessity for an expert except in doubtful cases. (4) Employment of the same character of signals for testing as is used in daily routine. (5) Placing the eye during testing at a distance necessary for future safety. (6) Bringing the eye during testing directly before the true condition of weather experienced as it is upon duty. (7) Test and match colors all graduated in proportionate size.

CASE OF EMBOLISM OF THE CENTRAL RETINAL ARTERY,

by DR. CHARLES A. OLIVER, Philadelphia.

The patient, a young man, was seen October 5, 1887. Twenty-six hours previously, while slowly walking in the shade, he was suddenly seized with blindness in the left eye. There were no other symptoms, and there had been no previous illness. The right eye was normal. Ophthalmoscopic examination of left eye showed clear media; nerve substance of a grey tint and swelling of the retina. All the retinal vessels were reduced in size. The veins were somewhat contracted, especially toward the nerve entrance. The characteristic cherry spot in the macular region was distinct. There was a small hæmorrhage out from the disk. Careful physical examination failed to reveal any lesion in other parts of the body. The case was kept under observation for some time, but there was no return of vision, the patient remaining completely blind in the left eye.

DISCUSSION.

DR. H. D. NOYES, New York. The result of autopsies shows that the great majority of these cases are really due to thrombosis and not to embolism.

Adjourned until Thursday morning.

THURSDAY, SECOND DAY. MORNING SESSION.

A CASE OF DOUBLE CONGENITAL IRIDEREMIA IN A CHILD WHOSE MOTHER EXHIBITED A CONGENITAL COLOBOMA OF EACH IRIS,

by DR. SAMUEL THEOBALD, Baltimore.

James O., aged eighteen months, was seen December 9, 1887. His mother brought him on account of the red appearance which the pupils presented. Upon

[1] Concluded from page 90.

examination, besides a congenital squint of the left eye, complete absence of each iris was discovered. The lenses were clear, and there seemed to be at least in the right eye, fairly good vision. The interest of the case lies in the fact, accidentally discovered, that there existed in the mother a congenital coloboma of each iris. In her right eye the coloboma was large, its direction being directly upwards; in the left eye it was somewhat smaller and was in an upward and outward direction. In neither eye was the choroid involved in the congenital effect. The mother volunteered the statement that an older child had had a similar appearance of the eyes, so that it is probable that to this mother with congenital coloboma, there was born not only one, but two children, with absence of the irides.

DISCUSSION.

DR. DAVID WEBSTER, New York. I think that the direction of the coloboma in the mother's eyes was unusual. I have seen a number of cases of congenital coloboma of the irides, but I do not recall an instance in which the coloboma was upwards. It is almost always downwards.

DR. B. ALEX. RANDALL, Philadelphia. Having had occasion to look up the literature of this subject, I can say that there are a number of cases reported of coloboma inwards or outwards, but not upwards. This case seems to be unique in this respect.

PUNCTURE OF THE RETINA FOR DETACHMENT,

by DR. T. Y. SUTPHEN, of Newark, N. J.

The results of the three operations were reported.

A male, sixty-two years of age sought treatment, April 1, 1887, for a cloudy appearance before the right eye. This he had noticed only a few days. He was near-sighted but had never used glasses. Examination R. S. $= \frac{1}{10}\frac{5}{5}$, raised to $\frac{1}{20}\frac{5}{5}$ by $-\frac{1}{16}$. Field of vision defective downwards and towards the median line. Tension slightly diminished. L. S. $= \frac{1}{10}\frac{5}{5}$, raised to $\frac{1}{3}\frac{5}{5}+$ by $-\frac{1}{16}$. Ophthalmoscope showed myopia with choroiditis in both eyes. In the right eye the retina was found detached in its upper and temporal portion. The patient refused to undergo vigorous treatment in bed. He was given iodide of potassium in gradually increasing doses, rest being enjoined.

Five months later the patient returned with commencing detachment in the upper and temporal portion of the left retina. He was then kept in bed for two weeks with the eyes bandaged, while profuse diaphoresis was frequently induced, but without benefit. He was then sent to the country, the iodide being continued. By December 1st there was in the right only perception of light; in the left there was vision confined to the outer and lower field. On this date puncture of the retina from beneath the detachment was made. Thorough antisepsis was employed; cocaine was instilled, a sickle-shaped needle was thrust into the globe between the insertion of the external and inferior recti muscles, on the equator and on a plane with the lens, it was pushed onward until it was thought that the retina had been pierced. It was then withdrawn with a sweeping motion, the object being to enlarge the opening in the retina. Atropine was instilled, the eyes bandaged and the patient ordered to keep quiet. The following day, the subretinal fluid had disappeared, field of vision was normal, a red reflex was obtained from the fundus in every direction and the patient could distinguish large objects. Bandage reapplied. Two days later patient could count finger at twelve feet, the retina appeared in the normal position but the vitreous was quite cloudy. The vision continued steadily to improve. December 10th, a similar operation was performed on the left eye. Two days later there was marked enlargement of the field of vision, but some detachment was still to be seen on the temporal side. December 16, field of vision in both eyes normal. No detachment of retina in either. The patient remained in bed twenty-eight days. February 10th, detachment began to reappear in the left eye. By March 3d it was as great as before. Needling was again performed, with the escape of very little subretinal fluid. March 5th, field again normal. April 1st, partial return of detachment in left eye. July 6th, seven months after first operation, S. R. $\frac{1}{10}\frac{5}{5}$, raised to $\frac{1}{3}\frac{5}{5}$ by $-\frac{1}{20}$. No return of detachment. Field of vision normal. Blindness for red. In the left eye almost complete detachment of the retina.

After referring to the history of the operation the speaker said that the interesting facts were these: The apparently perfect safety of the operation under modern antisepsis; one success and two failures under exactly similar conditions, barring the escape of the fluid outwards in the successful case; encouragement to try this operation in otherwise incurable cases; the absolute freedom from all reaction. The best results will probably follow where the operation follows closely upon the subsidence of the acute affection causing the detachment. The chances of success are increased by a free flow of fluid outwards. It was suggested that a narrow Graefe knife might be used after accurately measuring the depth of the detachment, provided the point be so directed that the wound in the retina shall be directly opposite the scleral puncture.

DISCUSSION.

DR. J. F. NOYES, Detroit: I have tried operative procedure in only one case. I drew off the fluid with a hypodermic syringe. After drawing off the fluid the retina returned to its normal position, and in it the outline of a small tumor was discovered. The detachment soon returned. The ball was enucleated one year later.

A CASE OF GLIOMA,

by Dr. E. P. CAPRON, of Providence.

The patient was a child three and-a-half years of age. The growth was removed, but has since involved the submaxillary glands and the glands in the neighborhood of the ear.

Photographs showing the appearances were presented.

DISCUSSION.

DR. D. B. ST. JOHN, Hartford: I would ask whether aid in the diagnosis between glioma and other affections is obtained by attention to the state of the tension.

DR. DAVID WEBSTER, New York: I think that I have never been able to detect any increase of tension until the second or inflammatory stage has been reached. Then there is always, I think, increase of tension. In at least two cases I have diagnosed glioma from the history with the existence of increased tension, when no tumor could be discovered. There is now on record a case in which Dr. C. R. Agnew removed both eyes of a child one year of age for glioma. This was fifteen years ago, and the individ-

ual is still living. In this case the diagnosis was verified by microscopical examination. In some cases where the diagnosis was made but enucleation refused, the patients are still alive, and the disease has not progressed, retrograde metamorphosis having, it is said, taken place.

The President, Dr. W. F. Norris: My impression is that in true glioma, retrogressive metamorphosis does not take place. Fatty degeneration may occur in parts of the growth, but I am not aware of a case in which the growth entirely disappeared. Such cases are, I think, instances of mistaken diagnoses. The diagnosis is difficult unless the growth has reached such a size that the vessels may be seen in it.

MODELS EXHIBITING REFRACTION BY CYLINDERS,

by Dr. Swan M. Burnett, Washington.

It was shown how the refraction and focal line change with the variation in the shape of the lens, and with the alteration of the angle of crossing of their axes. The models were made at his suggestion by Mr. C. E. Prentice, of New York. Diagrams were exhibited showing by geometrical construction how it was possible to tell the course of any given ray after its refraction by any two cylinders of differing power, and at any angle of crossing of their axes. A formula applicable to any axis of crossed cylinders, calculated by Mr. Prentice, was also shown.

Dr. B. Alex. Randall, Philadelphia, exhibited some drawings showing

ANOMALOUS OUTGROWTHS UPON THE OPTIC DISC,

and also drawings of

ANOMALIES OF THE RETINAL VESSELS.

DESIGNATION OF PRISMS BY THEIR REFRACTIVE POWER,

by Dr. Edward Jackson, Philadelphia.

The author pointed out the inconveniences and errors arising under the present method of designating the strength of prisms, and recommended their designation by their refractive power as much more accurate. A Committee consisting of Dr. H. D. Noyes, Dr. Edward Jackson, and Dr. Swan M. Burnett was appointed to take the matter into consideration and report at the next meeting.

EXTRACTION OF A PARTIALLY ABSORBED CALCAREOUS LENS,

by Dr. David Webster, of New York.

March 15, 1888, C. C., aged twenty-three, consulted Dr. Agnew and the author at the Manhattan Eye and Ear Hospital. She had phthisis bulbi, left, and in the right eye were the calcified remains of a mostly absorbed lens, with a discolored, atrophic-looking iris attached to the membranous mass by numerous adhesions. Visual field good. V = fingers at two feet. The vision of the left eye had been lost through a blow with a whip at the age of two years. A catarrh developed in the right eye some time afterwards. Seven years ago (1881), her sight having been lost four months, both eyes were operated on by a surgeon in another city several times. Violent inflammation followed one or more operations on each of the eyes. Eighteen months ago another needling was done by another surgeon, by which sight was somewhat improved. The atrophic eye, of late, has been painful and tender on pressure.

March 16th. Dr. Agnew enucleated the atrophic eyeball. A calcific plate was found in the choroid, and a small calcareous lens. While the patient was still under ether, he did an iridectomy on the right eye.

April 27th. Dr. Webster divided with Knapp's knife-needle two or three of the adhesions which were on the stretch. At least, one could be heard to snap when cut. An attempt to penetrate the thinnest-looking portion of the membranous mass failed. There was considerable effusion of blood, which was soon absorbed.

May 14th. An attempt to remove the pupillary obstruction with a sharp hook failed. Very little reaction.

June 6th. With a keratome bent on the flat, a wound was made as for iridectomy on the superior nasal corneal border. The pupillary obstruction was drawn out and cut off close to the cornea. Not a drop of vitreous escaped. There was some pain in the eye for three or four hours, probably the reaction from cocaine. Four days later pain again appeared, and was relieved by iced cloths.

June 18th. Fundus normal; no floating bodies in the vitreous, but the remaining portion of the pupillary membrane, which, by the way, was very thick and so tough that the iris-scissors would scarcely cut it, extends backward horizontally and flaps up and down with the movements of the eye.

June 22d. V = $\frac{20}{200}$, with $-\frac{1}{32}$. Reads Jaeger No. 1 with $+\frac{1}{2.25}$.

June 26th. Discharged, wearing the above spectacles.

Dr. Samuel Theobald, of Baltimore, exhibited an unusually long cilium. The hair was over an inch in length, and was removed from the eyelid of a young lady suffering with some conjunctival irritation. The other cilia were of the usual length.

The officers for the ensuing year are: President, Dr. W. F. Norris, Philadelphia; Vice-President, Dr. Hasket Derby, Boston; Corresponding Treasurer, Dr. J. S. Prout, Brooklyn; Recording Secretary, Dr. Samuel B. St. John, Hartford.

It was decided to hold a special meeting for the consideration of scientific matters only, September 19, 1888, at the Arlington Hotel, Washington, D. C.

The regular meeting will be held the third Wednesday in July, at the Pequot House, New London, Conn.

Adjourned.

AMERICAN OTOLOGICAL SOCIETY.[1]

A CONTRIBUTION TO THE ANATOMY OF THE ELEPHANT'S EAR,

by Dr. A. H. Buck, of New York,

The ear was exhibited, and the interesting points indicated. The external auditory canal is imbedded in air-containing cells, and is six and one-half inches long. The canal at the time of examination, was filled with desquamated material. In the middle ear, the handle of the hammer seems to lie in a horizontal plane. It is not vertical, as in the human being. The anterior part of the drum cavity is completely cut off from the posterior part. The eustachian tube comes up through a system of air-cells, and opens through one of them close to the drum membrane. Under the

[1] Concluded from page 88.

floor of the tympanic cavity, there are three septa making stall-like spaces. Two of these are quite long, six or seven inches. The labyrinth and other parts were not examined.

A CASE OF POLYPOID ANGIOMA OF THE EAR,

by DR. HUNTINGTON RICHARDS, of New York.

The patient, a girl six years of age, came under observation May 4, 1888, with profuse and badly smelling otorrhœa, unaccompanied by pain and dating only from the preceding February. Hearing seemed good; no bleeding from the ear had ever been observed. The general health was excellent. Examination of the affected ear revealed a polypoid mass almost occluding the canal. The color was deep purplish red. A considerable portion of the tumor was at once removed with the snare, and the remainder of the growth was extracted on the following day, having a small pedicle attached, seemingly to the outer surface of the drum membrane close to the prominence formed by the short process of the hammer. This stump was cauterized with chromic acid. Hæmorrhage from the cut surface of the growth was unusually profuse at both operations. The child's hearing is now excellent, although both membranes are depressed and of a dark grayish-red color. The removed growth was pronounced to be an angioma. Three micro-photographs showing the appearance of the growth were shown.

A CASE OF FALSE DRUM MEMBRANE.

by DR. HUNTINGTON RICHARDS of New York.

The patient, a man twenty-one years of age, was totally deaf in the affected ear. There was a vague history of an attack of otitis media in early childhood. The other ear presented the common appearance of otitis media purulenta chronica. Examination of the ear that was not discharging showed a membrane occluding the canal. It differed from the normal drum membrane in color, shape, relation of its plane to the long axis of the canal, and apparent thickness. It varied little in color from the skin lining the canal. The surface was perfectly smooth.

A triangular opening was made through this membrane; This caused no pain. Through this opening it was seen that there was no drum membrane, but the inner wall of the tympanic cavity came into view. The hearing was only slightly improved. When seen a few days later, no discharge had appeared! Since that time he has not returned to the infirmary.

DISCUSSION.

DR. S. SEXTON, New York. I have seen several such cases as that described in the last paper. In a case seen last year, I removed the membrane, and then took out the malleus and incus. This case made a good recovery. The improvement in hearing was decided. I would suggest this operation, in such cases, as a possible means of improving the hearing, for it opens up the tympanic cavity which is a good condenser of sound; and in the second place to prevent the accidental occurrence of imflammation in these parts when it might be difficult to obtain relief.

DR. T. Y. SUTPHEN, Newark. I have seen one or two cases of this trouble, which seems to me to be due to cicatricial closure of the external canal. It seems to me that the condition would be best spoken of as cicatricial closure of this canal.

DR. CHAS. J. KIPP, Newark. These cases result from granulations and I have watched the formation of these membranes. In treating this condition, I have incised the membrane and put in laminaria bougies, and it has disappeared.

DR. A. MATTHEWSON, Brooklyn. A lady was under my care for some time with an eczematous condition of the external meatus. She then passed from observation. Some time later she presented herself with a dish-like closure of the external canal. This was not complete, as there was a small opening in the centre. I dilated this opening with laminaria bougies, and the ear was left in perfect condition.

DR. SAMUEL THEOBALD, Baltimore. The members may recall a case which I reported, in which there was occlusion of both external canals. There was a history of suppuration, and no doubt there was ulceration and gradual closure.

DR. CHARLES H. BURNETT, Philadelphia. I have seen several of these cases of dermoid diaphragms in the canal. Three of these were in private practice. One was in an old man, and it remained imperforate during the whole time he was under observation. The other cases were perforate when they came to me. There was slight discharge, which I checked, and the perforation healed. In one case the discharge returned after a short time, and the perforation reappeared. Under treatment, it healed; and I have reason to believe has remained closed since, a period of four or five years. In the other case it remained closed for a year, when the opening returned with slight discharge. The discharge ceased under treatment, the opening closed, and has remained closed.

DR. B. ALEX. RANDALL, Philadelphia. In the case of a boy twelve years old, in which there was closure of the meatus as a result of injury with forceps during labor, I excised the diaphragm; the cavity was thoroughly washed out; the case was then treated in the ordinary way. The hearing obtained was certainly one-fourth of the normal.

EVENING SESSION.

THE FLEXIBLE CATHETER AS A DRAINAGE-TUBE, WITH CASES,

by DR. J. B. EMERSON, of New York.

The author cited several cases exhibiting the use of the flexible catheter as a drainage-tube. With deeply-seated inflammation of the auditory canal or mastoid cells, maintainance of drainage through a fistula is a necessity; and to prevent closure of the fistula either by granular growth or natural healing is important.

Dr. Emerson recommends the use of the flexible catheter as generally the best means to employ, and states his reasons to be the comparative comfort and safety, together with convenience of control by both surgeon and patient. The efficiency observed in the use of the flexible catheter was also referred to.

DISCUSSION.

DR. O. D. POMEROY, New York. Some years ago I recommended the use of a soft rubber tube in suppurative otitis in little children with closure of the canal, with no changes except swelling. The canals are so small that the tube cannot be pushed in in the ordinary manner. A piece of small tubing was hooked to the extremity of a metal probe which passed through it. The tube was then drawn tight thus reducing its size. In this way it could be readily introduced,

When the tube was released, it tended to resume its proper size, and the probe was withdrawn. Almost all these cases did well.

THREE CASES OF TRANSIENT BILATERAL HORIZONTAL NYSTAGMUS IN CONNECTION WITH PURULENT INFLAMMATION OF THE MIDDLE EAR,

by DR. CHARLES J. KIPP, Newark.

CASE I. A young man, twenty-one years of age, had had otorrhœa seven or eight years previously. Three months before coming under observation he had an acute exacerbation and suffered intensely with pain in the ear and head. The otorrhœa much diminished. Two or three weeks later he came stating that he saw objects double, was dizzy and could not walk. There was marked nystagmus in a horizontal direction. The vertigo and nystagmus continued four days. With the cessation of the nystagmus the vertigo disappeared.

CASE II. A young man treated six years previously for acute otitis media purulenta, ending in recovery, appeared in March with an acute attack. Paracentesis was performed. The pain, however, continued for a long time. Finally, swelling developed behind the mastoid, and this was accompanied with several epileptiform attacks. One day, pressing on the swelling pus poured from the canal. With this there was a sudden jerk of the head and nystagmus. The latter continued for about ten minutes; this was produced every time pressure was made on the mastoid. The mastoid was subsequently opened; since then there has been improvement.

CASE III. A young man, after exposure, was seized with intense pain in the ear followed by otorrhœa. When he came under observation there was great pain. This was not relieved by treatment but continued two or three weeks. Then a swelling appeared below the ear. This was incised and a large quantity of pus evacuated with relief to the pain. Some days later while washing out the cavity, the fluid came through the ear when considerable force was used. At the same time there was a jerk of the head and nystagmus continuing several minutes. This could always be produced by making a forcible injection.

DISCUSSION.

DR. O. D. POMEROY, New York. Reference has been made to epileptic symptoms in one of the cases. I have recently seen a case of epilepsy in which the exciting cause was suppuration of the middle ear. With recovery from the ear disease the convulsions ceased and have not returned.

AN IMPROVED AURAL SNARE,

was exhibited by DR. J. O. TANSLEY, of New York.

The snare was devised to overcome an objection to the ordinary Wild snare, that is, the little jerk and rebound of the instrument when the growth is cut through. The instrument exhibited consists of a small tube, through which the wire passes to be connected with a small bobbin by the turning of which it is gradually shortened.

A paper by DR. S. SEXTON, New York, on

FOREIGN BODIES IN THE EXTERNAL AUDITORY CANAL,

was read by title.

EXECUTIVE SESSION.

The following officers were elected: *President*, Dr. J. S. Prout, Brooklyn; *Vice-President*, Dr. Gorham Bacon, New York; *Secretary* and *Treasurer*, Dr. J. J. B. Vermyne, New Bedford, Mass. *Committee on Membership*, Drs. A. Matthewson, D. B. St. John Roosa, and John Green. *Delegate to the Congress of American Physicians and Surgeons*, Dr. W. H. Carmalt, New Haven; *Alternate*, Dr. G. Bacon, New York.

The Society then adjourned, to meet at the Arlington Hotel, Washington, D. C., Tuesday, September 18, 1888.

Recent Literature.

The Applied Anatomy of the Nervous System. By AMBROSE L. RANNEY, A.M., M.D. Second edition, rewritten, enlarged and profusely illustrated. New York: D. Appleton & Co. 1888.

As the author states in his preface, the success of the first edition of this book has induced him to prepare another which is practically a new work. The difficulties of the nervous system make its applied anatomy very welcome. The author brings much learning to his work and gives an excellent account of the central nervous system in what we may call the diagramatic style. We are best pleased with the chapters on the brain. It is as clearly and simply treated as its complexity permits. We think there is but little of it that a good student with a fair knowledge of the coarser anatomy of the organ could not grasp. The author shows commendable prudence in the matter of accepting theories, but he may appear to some rather too free in giving the discordant views of different authorities. This is confusing to the student, but in the uncertainty that hangs over so much of this subject, it can hardly be avoided. The treatment of the nerves, especially the spinal nerves, is to our mind, rather less satisfactory. We will not say that there is too much of Hilton, whose views, if at times fantastic, are still fascinating and valuable, but there is too little of recent observations. The causes of the curious diversities of paralysis occasionally following division of some of the nerves of the forearm, require more extended discussion.

The book is profusely illustrated with figures of very unequal merit and appropriateness. There are beautiful plates showing cerebral localizations according to Horsley and Beevor. The diagrams are well-conceived and well-executed. Illustrations of minute anatomy seem out of place in a work of this kind. We can see no advantage in representing nerve-fibres, but if the author thinks otherwise he should at least give us something better than Kölliker's figure of thirty years ago, more or less, representing what we now know to be changed and distorted elements. The description of the figure of the separated brachial plexus from Sappey (p. 666), is incorrect. The musculo-cutaneous nerve is called the musculo-spiral, and the latter, from too close a following of the French idiom, is called the radial. This, however, is nothing to the blunders in the description of the plate on the next page. The median nerve is called the musculo-cutaneous, the ulnar the median, the musculo-cutaneous the musculo-spiral. The introduction of tests for astigmatism is, we think, irrelevant. The text is not free from error that moderate care would prevent. In the

chapter on the membranes of the brain the arachnoid is correctly described as a membrane between the dura and pia, and having the subdural and subarachnoid spaces on either side of it. We are told that "it is continuous with the membrane filling the same relative position in the spinal canal, known as the 'spinal arachnoid,'" but when we turn to the description of the latter we find, to our confusion, that it, "like all other serous membranes, consists of a closed sac with a cavity between its two layers." We regret these defects the more because we can heartily commend the book as a whole. It will, we are sure, be useful to both teachers and students. T. D.

The Massage Case. By CYRIL BENNETT. London: S. Fisher Unwin. Boston: Cupples & Hurd.

This is the first novel that has come to our notice in which massage takes a prominent part. It is a very good story told with the simplicity and earnestness of truth, and probably part, if not all of it, is founded on fact. It is about a young lady worn out and sad from the illness and death of her mother, who, simply needed rest and change; but instead was sent by a managing aunt to a Nursing Home for imprisonment, in order to break up an injudicious love match. The patient quickly discovered that she was the only lady in the Home, and that she was being regaled with rather too much tobacco smoke, which proceeded from the rooms of other guests. The nurse was ordered to give her massage for two hours daily at first, and this was to be gradually increased to three hours daily. "It consisted of violent pinching from head to foot, and was a torture worthy only of the Spanish Inquisition." The administration of the electricity was no better. We need not go from home to find Nursing Homes and Private Hospitals of this kind.

There are some keen delineations of character in the book. The eminently successful practitioner, who overwhelms people with his powerful individuality, and compels them into saying and doing what he means them to say and do, is well described. So also is the highly appreciated old-fashioned nurse, who has become a little too knowing, and who freely expresses her opinion about massage, thus: "To begin with, it's very seldom done quite right. The doctors don't know how it ought to be done, and they depend on the nurses; and in nine cases out of ten the nurses have been taught badly, and it's the blind leading the blind." But what became of the patient? That is just how our readers can while away a few hours very pleasantly in finding out for themselves, during which they will not be bored with massage. D. G.

— The increase of medical men in England from 1881 to 1886 was 1,908, being more than twice as many as the proportionate increase in population required. Yet in this increase, which is properly deplored by the profession, leaves our English brethren considerably better off than us. In 1881 there were 1,747 persons (that is possible patients) to each practitioner; in 1886, 1,662. In Sheffield there now are 2,593 persons to each practitioner; in Liverpool, 1,564; in Bristol, 1,232; in London, 939; while in Brighton, which is spoken of as a most unhappy place for a doctor, there 726 persons to each practitioner; about the same ratio, we believe, which obtains on the average throughout the United States.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 2, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

THE SURGICAL TREATMENT OF INTESTINAL OBSTRUCTION.

THE recent publication in full of Senn's experimental work[1] arouses anew the interest in this most serious class of cases. Encouraged by the success due to the modern method of dealing with gunshot wounds of the intestine, the writer determined to investigate the operative treatment of intestinal obstruction which constitutes, as he justly says, one of the darkest and most unsatisfactory chapters in the wide domain of abdominal surgery. His aim has been to devise if possible a method which should not only remove or render harmless the cause of the obstruction, but also by the same operation restore at once the continuity of the intestine.

For this purpose he has studied the subject in a most thorough manner. One hundred and fifty operations were performed on animals requiring a period of one and one-half years for their completion and the observation of their results. Not only were new operative procedures for the relief of intestinal obstruction thoroughly tested, but also the conditions resulting from the principal varieties of such affections. In this manner some very valuable data have been obtained, which in part confirm results of other observers, in part introduces methods and technique greatly increasing the possibility for relief of these cases. Most conspicuous among these results are: First: An improved method of uniting a resected intestine, which is a modification of the "Jobert" suture, if such a marked modification may be so described. Second: A method of relieving obstruction by forming anastomoses by means of "approximating plates." Third: The transplantation of omental flaps to render more certain the immediate union of intestinal wounds. These methods, according to Senn's experimental work, certainly do have decided advantages over the present method of uniting intestinal wounds by suture only, since they materially shorten the time required for such operations, a factor of the greatest

[1] Reprint. Ann. of Surg., 1888, January to June.

importance, and apparently increase the chances of immediate union, the failure to obtain which, usually costs the patient his life. They also avoid in a majority of cases the necessity of colotomy..

The interesting question of how extensively the intestine can be resected with safety, which Hahn [2] discussed some time since, and to the answer of which the cases of Kœberlé, Kocher and Baum contribute valuable data, has been investigated. In cases of multiple strictures, ulcerations, gunshot wounds or gangrene, where the lesions are large or in close proximity, excessive resection is unavoidable, and an accurate knowledge of the extent of intestine which can be removed with impunity, becomes of vital importance. It is not so much in regard to the immediate danger from so severe an operation, which is proportionate to the extent excised, but with reference to the remote risks from inanition resulting from the consequent impairment of digestion and absorption. In cats and dogs removal of more than one-half of the small intestine is dangerous to life. Excision of the entire colon invariably caused the death of the animal by shock due to the operation, and is, therefore, impracticable. These results coincide with Hahn's statement that loss of a large extent of small intestine is better tolerated than the resection of an equal amount of ileum and colon. It leaves unanswered the question as to whether the resection of a portion of the colon is more fatal than an equal amount of small intestine, except when the amount equals the entire colon, the removal of which was found to be invariably fatal.

The physiological exclusion of a certain portion of the intestinal tract is demonstrated to be a less dangerous operation than excision. This, in addition to the rapidity with which this can be accomplished, urge its employment rather than resection. It is especially of value where resection is impracticable, or where the pathological conditions which have caused the obstruction do not constitute *per se* an immediate or remote danger to life. An interesting and important fact in connection with these anastomoses is that the excluded portion of the intestine including the obstruction, does not become the seat of fæcal accumulation, and Senn claims that peristaltic or anti-peristaltic action is effective in forcing back into the active current of intestinal circulation whatever portion of the intestinal contents may have entered this isolated tract. As soon as a free communication is established through the artificial opening a progressive atrophy of this occluded portion occurs.

The value and importance of Senn's method of anastomoses, which permits the restoration of the continuity of the intestine and enables the surgeon to avoid colotomy, an operation often attended by such deplorable results that many patients becoming objects of disgust to themselves and unendurable to their friends prefer death to such an existence, can be readily appreciated by one who has had to operate when the nature of the obstruction rendered its removal impossible. Intestinal anastomoses furnish a means of escape from this distressing alternative, and only in inoperable cases of rectal cancer is immediate restoration of the continuity of the intestine contraindicated. It is especially desirable when an artificial anus for relief of obstruction in the upper part of the ileum or jejunum isolates so large an absorbing surface that the unfortunate victim dies from starvation. Gastro-enterostomy, jejuno-ileostomy, ileo-ileostomy, ileo-colostomy, ileo-rectostomy, colo-rectostomy, are terms which give some idea of the operations which this method of anastamoses by lateral apposition and approximation-plates renders possible.

Among the many facts obtained by Senn from his experimental work, the following are of especial importance:

Operations which reduce the lumen of the intestine to less than one-half its normal size cause danger from obstruction and perforation. Gangrene and perforation due to defective blood-supply invariably occur when the integrity of the mesenteric attachment is destroyed. Fæcal accumulation above the seat of an invagination is one of the most important factors preventing spontaneous reduction, and causing gangrene with perforation. This gives, perhaps, an additional importance to gastric *lavage* as a means of removing such accumulations, and thus aiding reduction.

Ileo-cæcal invagination, when recent, is often reducible by distension of the colon with water, but the greatest gentleness should be used, since over-distension causes multiple longitudinal lacerations of the peritoneal coat, an accident from which the gravest consequences may ensue.

The omental "flap" or "graft" is a procedure which furnishes an additional protection against perforation in all cases of circular resections.

Intestinal anastomosis is preferable to resection or circular enterorrhaphy in all cases when it is impossible or impracticable to remove the cause of the obstruction; or where the obstruction, from its pathological character, is not an intrinsic source of danger. The method of lateral apposition with bone-plates should always be used in gastro-enterostomy, jejuno-ileostomy, and ileo-iliostomy. Obstruction in the colon and cæcum, and all cases of irreducible ileo-cæcal invagination, when gangrene or impending perforation does not contraindicate the procedure, should be relieved by the proposed method of anastomoses. or by lateral implantation of the ileum into the colon or rectum. Gangrene or perforation requires excision of the invaginated portion, followed by immediate closure of the resected ends with ileo-colostomy or ileo-rectostomy.

Lateral "appo-ition," or "implantation," permits the restoration of the canal where circular enterorrhaphy is impossible on account of the difference in size of the resected ends.

Scarification of approximated peritoneal surfaces hastens the formation of adhesions and the healing of intestinal wounds.

THE MIND-CURE AND FAITH-CURE DELUSION.

REV. LEONARD WOOLSEY BACON, in a recent number of the *Forum*, discusses the "Mind-Cure" and the "Faith-Cure," and says some sensible things, for which he deserves the respect of all doctors.

The mind-cure, which, according to its leading representatives, is only a synonym for what is also called "Christian science," is, says Mr. Bacon, "an artless application to the subject of pain and disease of the well-known Berkelian argument for the non-existence of the material universe, or the argument which admits no refutation and produces no conviction." Since sickness and pain are only forms of consciousness, having no objective reality, what more obvious than that they should be treated as such? The seat of disease being the mind, let the mind be treated with mental influences, and not the body with drugs — admitting for a moment the popular prejudice that there are such things as drugs and bodies. This method of dealing with illusive diseases by an illusive treatment at the hands of an illusive practitioner has much to recommend it, if only it can be consistently carried out. But at one critical point it has constantly and conspicuously failed. The fee of the physician (or "metaphysician," as he delights to call himself), remains up to the present date a hard, metallic, refractory, and objective fact, which obstinately refuses to immaterialize itself." "Until the mind-cure makes this final and splendid advance, by which the doctor's bill shall be satisfied through his inward contemplation of ideal gold and greenbacks, its chief value must continue to lie in the popular protest which it makes against materialism by means of its funny books and its considerable number of devotees."

Concerning the "faith-cure," Rev. Mr. Bacon, from the standpoint of its advocates, presents a cogent argument to show that a flagrant error in exegesis has been committed, which vitiates the inferences which have legitimatized this system of supernatural therapeutics. "It relies upon an alleged divine promise, which it claims to find in the epistle of James (Chap. v: 14), and consists in abstaining from medical advice and treatment of every sort, and in sending, instead, for the male and female practitioners of the 'cure,' who apply, instead, a sacramental 'anointing with oil,' together with prayer. It is claimed that the divine promise is express, clear, and unmistakable that the anointing and prayer shall be followed by the healing of the sick, although when this fails to follow, there is always some adequate explanation at hand to save the credit of the divine word. And it is further claimed that in the devotees of this system we have a shining example of primitive and apostolic piety, a childlike faith, an obedient following of the letter of the divine word, which puts the rationalizing half-belief of ordinary modern Christians to shame."

Mr. Bacon discusses this latter claim and the Scripture exegesis. The claim, he says, is not to be tolerated. It is quite without foundation. "Among these high livers and 'faith-curers' there are some more or less intelligent people, and some not so good. As we meet them casually, we commonly find them pitiably bloated with spiritual self-conceit. Their childlike following of Scripture is apt to stand in a huge delight in their favorite scraps of the sacred text and their favorite blunders of interpretation. As a class, they are not one whit better than the plain, ordinary Christian who loves God and his neighbor, does his daily work faithfully, pays his debts a hundred cents to the dollar; and in point of humility and meekness and intelligent understanding of the Scriptures, they are decidedly worse."

In considering the interpretation of the famous text of the Epistle of James, Mr. Bacon shows: (1) That this verse does not inculcate or imply the instituting of a sacrament of religious unction for healing to be observed by all Christians; nor is there any allusion in the other apostolic writings to the practice of such a sacrament, nor is it recognized in the early Church after the Apostle's days. (2) The word *anointing* is sometimes spoken of in the New Testament in a secular sense, with reference to its cosmetic, antiseptic, hygienic, and medicinal uses. For this sense, a wholly secular word is used, which is never employed in a religious application; it is, says Mr. Bacon, a significant fact that this secular word is the one which we find in the text. The medicinal use of oil as an embrocation "was very common and important in the therapeutics of that age and region." The Good Samaritan, practicing the surgery of the period, poured oil and wine into his patient's wounds. Celsus, Pliny, Josephus, etc., mention oil baths and oil rubbings as an important part of the therapeutic applications of the times. (3) Having shown that the "anointing with oil," means simply resorting to the ordinary curative means of the day, Mr. Bacon discusses the meaning of "sending for the elders of the Church." This body of gifted men, he says, the leaders of the Christian brotherhood, included men endowed with talents fitting them to serve their fellow-believers, not only as leaders in worship and teaching, but also in more secular needs. These "gifts" were not necessarily miraculous. The catalogue of them in Corinthians (I Cor., xii: 8–10), makes separate mention of the gift of miracles among other gifts which clearly were not miraculous. And a notable fact it is that the *gift of healing* is not included in the gift of miracle-working, but is mentioned separately with gifts of another kind. Among the talents bestowed for the good of the Church, was a talent for teaching, a talent for exhorting, a talent for managing affairs, a talent for comforting the sick and sorrowful, and a talent for treating diseases. There is not a particle of evidence that this last gift was any more miraculous than the others, and there is distinct evidence to the contrary." By considerations such as the above, Mr. Bacon shows that the text in James "begins to grow lucid in the light of the other Scriptures," and "congruous with the plain, hearty, divine-human, common-sense that is the

preëminent characteristic of this Epistle." Rightly understood, then, the text, instead of giving any encouragement for the founding of a "faith hospital," or the establishment of camp-meetings for "faith cures," is "the counsel of a wise spiritual leader, given apparently in a time of some prevailing epidemic, to the Church, that at the first outbreak of sickness in a family, instead of beginning on the case with a little amateur domestic practice, or with some simple prescription from the neighbors, or with the incantations of some heathen quack or 'medicine man,' they should at once send for the gifted and experienced professional physicians of the community, as well as for the spiritual counsellors and comforters."

The above interpretation of a much misunderstood and much perverted text, will pass for good Nineteenth Century Scripture.

LEPROSY IN THE SANDWICH ISLANDS.

The leprosy of the Sandwich Islands is of especial interest to us in the United States because of our proximity to the Islands, and especially because the efforts of the Government to control the spread of the disease have a certain tendency to drive lepers to us to escape the isolation to which they would be condemned if they remained. The report of the Hawaiian Board of Health, just received, is devoted largely to questions connected with leprosy, and contains many interesting tables and statements concerning the disease and its progress. In the first place, the President of the Board states his conviction that the medical profession of the Islands are unanimous in the belief that leprosy is a communicable disease, and that every leper is a possible source of contagion to all who may come into more or less intimate contact with him. Leprosy was first clearly made out in the Islands about 1840. In 1868, the number of lepers was supposed to be 274. On March 31, 1888, the number of lepers at the leper settlement on Molokai was 749, 495 males and 254 females. The number of lepers still at large cannot be given with accuracy, but it is not over-estimating their number to put it at 644. No person is consigned to the leper settlement without his being declared to be a confirmed leper by, at least, three competent physicians.

The greatest obstacle to be overcome in carrying out the law of segregation lies in the fact that the Hawaiians themselves refuse to believe that leprosy is a communicable disease. Marriages between leprous and non-leprous individuals are freely contracted, and the most reprehensible intimacies are not prevented by patent evidences of the disease, and public sentiment does not support the executive in carrying out existing laws. One of the most embarrassing questions that the Board of Health is called upon to settle is who and how many of the relatives of the afflicted shall be allowed to accompany them to the leper settlement. It is necessary to retain at the leper settlement a certain number of non-leprous individuals for various services as helpers, and the number of applicants for such positions is largely in excess of the demand. In April last, a Commission visited the leper settlement and examined those on the list of lepers who thought themselves wrongly classified, and also those not on the list who were thought by themselves or others to be lepers. Of 66 helpers (kokuas) examined by the Commission who had resided with the lepers for various lengths of time, and who, presumably, entered the settlement without the suspicion of leprosy in their bodies, 23 were found to present unmistakable signs of leprosy, and 11 more were designated as suspected lepers — a strong argument in the eyes of the Commission of the contagiousness of the disease.

Of the newspaper report as to the appearance of leprosy in a condemned criminal pardoned for the sake of experiment, no mention is made in the report.

The Board of Health is not satisfied with attempts to stamp out the disease by segregation, but is active in efforts to improve the condition of the lepers themselves. The methods of Unna are already in use in a special leper hospital, and the Board publishes a letter to Unna, in which they appeal to him for suggestions and assistance, asking him to receive patients to be sent to him at Hamburgh, or to suggest some one in his confidence who will put his services at the disposal of the Hawaiian Government.

MEDICAL NOTES.

— A new position at the Boston City Hospital has been created; namely, that of ophthalmic and aural interne. An examination of candidates for the term from September 1st next to January 1, 1889, is soon to be held. Candidates must send their names to Dr. E. J. Forster, at the Hospital, secretary of the staff, before August 8th.

— A full report of a lecture on personal identification, by Mr. Francis Galton, appears in *Nature* for June 21st and June 28th. Mr. Galton here presents a practical application of his favorite pursuit, the accurate description of physical and mental peculiarities. He proposes a very ingenious scale of divergencies from the normal for any one feature, and has even invented a mechanical device by which the tedious labor of arranging a large number of such observations can be much abbreviated. The anthropometrical laboratory, at which any one can, under proper restrictions, have a record made of his chief physical measurements, is now open in London, and promises to yield valuable material for this line of study. In connection with this work, Mr. Galton has studied the striations of the human fingers, and is able to corroborate the value attributed to them as a means of identification. These markings are easily obtained, and the variety of them is larger than one would *à priori* imagine. The markings of a finger of Sir William Herschell made in 1860 and 1888 respectively are figured, and show a striking similarity. The difference in age of the two

prints testifies to the wearing of the epidermis. The study is still in its infancy; but the success of such measurements for identifying criminals, as exhibited in France, promises to draw more general notice to the subject. — *Science*, July 27.

NEW YORK.

— The Hudson County Medical Association of New Jersey, which was recently formed to prevent the swindling of members of the profession by patients who are able to pay for attendance, but refuse to do so, met at Taylor's Hotel, Jersey City, on July 25th, and adopted a constitution. It provides for the employment of a collector, in whose hands all questionable bills are to be placed, and who will be allowed twenty-five per cent. on all such bills collected. He is to report those from whom collections cannot be made to the Board of Governors, and the members of the Association are to be warned by circular against trusting them.

— A young man, twenty-two years of age, recently died at the Presbyterian Hospital from hæmorrhage resulting from the extraction of a molar in the right lower jaw.

— A special meeting of the Fifth District Branch of the New York State Medical Association was held at the Sherman House, Babylon, Long Island, on the 31st of July, when papers were read by Drs. J. G. Truax, of New York, William Govan, of Rockland County, and others.

Correspondence.

OVARIOTOMY IN AGE.

LONDON, ENG., July 9, 1888.

MR. EDITOR, — I have read Dr. Billings's letter on this subject with great interest. It will clear up a very old text-book error, and I will do my best to make known the results of his "examination of the *original* records" of the cases to which I referred. I must note, however, that, had I not written the letter which you kindly inserted in your journal of June 7th, the error would have been overlooked.

I entirely agree with Dr. Billings's remarks on the danger of second-hand quotations; yet a second-hand quotation is surely a *record* when it is to be found in the works of standard authors like Olshausen and Peaslee. In Dr. Homans's valuable contribution, published in your journal of May 3d, I find the words: "Dr. Lorini made a *thorough* search without finding any case *recorded* older than seventy-eight years of age." This sentence, written by Dr. Homans, is immediately followed by Dr. Lorini's letter, which refers to "the subject of ovariotomy in women of eighty years and over." The writer has "failed to find a single case *recorded* in any journal, pamphlet or book." Thus, in the above quotations there is nothing about *original* records, of which Dr. Billings speaks. Indeed, that distinguished surgeon admits that it was my letter which led to the "examination of the *original* records" of the cases to which I referred. Again, a *false* record is still a record; hence it is incorrect to imply that "not a single case" of ovariotomy in women of eighty years and over is "*recorded* in any journal, pamphlet or book." Hence, had I not written my letter, several important fallacies would have escaped detection. It led to "the examination of *original* records," and to a specific declaration from Dr. Billings as to the originality of the said records. Dr. Lorini's letter, as I have above shown, said nothing about originality.

Thus, there *are* records of ovariotomy in patients of eighty years and over, but these records are mostly second-hand and inaccurate. Drs. Billings and Lorini, however, undoubtedly overlooked Schröder's cases until my letter led to the examination of "original records." Why does Dr. Billings say "the authority is *merely* a footnote by Schröder in his 'Krankheite der Weiblischen Geschlechts' (*Leipzig*, 1887, page 640), as follows: 'Ich selbst habe Kranke im 79 und 80 jahre mit Glück operirt?'" Why *merely*? Surely we have here an "original record?" Is a footnote of this kind in an original work to be distrusted? There can be no suspicion of misprinted figures (such as led me into error in respect to Miner's case), for the note refers to this passage in the text: "Höhes Alter und Mangelhafter Kräftezustand contraindiciren einfachere Operationen nicht."

I admit my oversight regarding Atlee, and am much indebted to Drs. Billings and Lorini for correction as to the remarkable mistake "eighty-two" for "thirty-two," which I copied from a widely-read American publication. The credit due to Dr. Homans for his successful ovariotomy in a patient aged eighty-two, and to your journal for the "original record" of the case is incontestable.

I remain, dear sir, yours truly,

ALBAN DORAN.

PRIVATE MENTAL SANITARIA AND THE INEBRIETIES.

TO THE EDITOR, — The officers of the Massachusetts Medical Society, in whose hands the paper was by their requirement, caused or permitted to be published in your issue of the 21st ult. an abstract of a paper entitled "Private Mental Sanitaria and the Inebrieties," which paper was read and "discussed" before the recent anniversary meeting of that Society in Boston. The abstract was not shown to the author of the paper, nor was he informed that it was to be made or printed. Whether it was made by the known officers of the Society, by its "experts," or by this journal, does not appear. But the writer is unwilling that his views, as given in the paper in question, should be left with the medical public in the form of the incomplete skeleton that has been given out as above described — minus a vertebra or so and the phalanges indicis. The question really considered is one of some importance. The members who, by invitation of Society officers, spoke in the meeting just after the paper was read, have edited their (as delivered) unwritten remarks, while the author of the paper was not invited by the managers to close the discussion. It is probable, therefore, that the writer whose paper has had so ample an oblique light cast or thrust upon it, will not come into the court of this journal's equity quite outlawed when he solicits a little space. Your readers, it may for your sake be hoped, are a larger audience than that to which the paper was read.

The position taken by the paper regarded the following suggestion or claim: That in the coming legislation of Massachusetts, when it is expected and hoped by all that a special institution for inebriates will be decreed, and hoped that inebriates will be committible by judicial process to such, very desirable institution, that then the existing law which allows the commitment of the inebriate to the public and private lunatic hospitals of the state shall not be abrogated. If all our lunatic hospitals should not treat more than a dozen such patients in a twelvemonth, after the new provision is made, let that dozen be committed by law. It is comparatively easy to manage, to treat, sometimes to cure, such cases, *when committed*. If not committed, and thus restrained under proper authority, system and method, they are perhaps the most difficult sort one has to control, and as hard to cure as a broken bone without a splint. The power, aid and sanction conferred by the commitment procedure ought not to be withdrawn from any who shall be entrusted with the duty, or given the permission, to treat the inebrieties. It may fairly be assumed that the public and private superintendents in lunacy are competent and trustworthy for

the responsibility in question, or, if not, can be put out of the way for cause. Let them not be emasculated while *locum tenentes*.

The importance of this simple and narrow contention will not be the less appreciated when it is known, what the writer is in a position to state, that those who drew the law now in force, whose continuance is herein contended for, did not intend by means of it to ordain the commitment of inebriates to the *private* lunatic hospitals of the State, but to prevent such commitment. The failure of this part of their purpose, through overruling judicial construction of their words has been the fortuitous means of great good to a number of sufferers from addictions already.

The paper narrated that cures of inebriety in its various forms had been attained in the lunatic institutions under the charge, respectively, of our illustrious fellow, Dr. Pliny Earle, and of the writer, one a state, and the other a private hospital. And it would seem that, if under auspices of personal eminence and skill, and other conditions so diverse and separated as these — like alpha and omega, top and bottom — success had been reached, then, through the whole alphabet of varying abilities in superintendents much good work might confidently be expected.

Institutions of all names and functions are but servants of the public weal. They do not exist for the sake of pleasing certain specialists, or to exploit their ideas. It does not follow that an inebriate should not be sent to a lunatic hospital because some one's views of classification will be offended, nor because the patient may tax the hospital officers. It may be that he prefers the lunatic institution of the two, and that he will behave better and gain faster there. If so, and if the superintendent is willing to admit him, why should not the courts have discretion to commit him to a lunatic hospital, even after we have the institution for inebriates?

But it would be a signal injustice and burden to the private hospitals to deprive them of their right to treat inebriates as committed patients. To them are likely to go in the future, as have gone in the past, the superior grade of habituates, more or less willingly, who would not, short of sheer compulsion, enter the pan-Massachusetts inebriate pound. Indeed, the writer must admit that, if he were in need of succor from any addiction, he would, for all the inebriate asylum, prefer to be committed, for example, to the care of that veteran and able alienist, Dr. Merrick Bemis, if he would accept the duty; and like sentiments are very common, as shown by inquiry. These patients have some right of choice.

The private hospitals are entitled to a fair chance to support themselves, for they have no manner of aid in that direction; and, as said already, commitment is a powerful adjuvant to the treatment anywhere. Nor should it be quite forgotten that the inebriate clientèle of the private hospitals includes patients from other States and countries in considerable proportion. The laws of Massachusetts should enable its guest-receiving institutions to take the best possible care of its ailing commorant population, who have come within our borders for the sole purpose of recovering their health.

Shady Lawn Hospital,
17, July, 1888.

[The brief mention of Dr. Thompson's paper in the Report of the Society Meeting to which reference is made, was, of course, the work of the Journal's reporter. — Ed.]

REPORTED MORTALITY FOR THE WEEK ENDING JULY 21, 1888.

Cities.	Estimated Population for 1888.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Diarrhœal Diseases.	Typhoid Fever.	Diph. & Croup.

Northampton	13,419	6	3	16.66	16.66	16.66	—	

Deaths reported 2,703: under five years of age 1,532; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,005, consumption 269, acute lung diseases 127, diarrhœal diseases 757, diphtheria and croup 74, typhoid fever 42, whooping-cough 39, scarlet fever 26, malarial fever 23, measles 21, puerperal fever eight, cerebro-spinal meningitis seven, small-pox three. From whooping-cough, New York 21, New Orleans and Washington four each. Baltimore three, Philadelphia and Pittsburgh two each, St. Louis, Boston and Fitchburg one each. From scarlet fever New York 21, Pittsburgh two, Philadelphia, Portland and Fitchburg one each. From malarial fever, New Orleans eight, New York five, Philadelphia three, St. Louis and Nashville two each, Baltimore, Cincinnati and Charleston one each. From measles New York 16, Baltimore and Lawrence two each, Pittsburgh one. From puerperal fever, New York five, Philadelphia two, Washington one. From cerebro-spinal meningitis, New York two, Philadelphia, New Orleans, Worcester, Somerville and Brockton one each. From small-pox Philadelphia three.

In 23 cities and greater towns of Massachusetts with an estimated population of 1,035,396, the total death-rate for the week was 21.33 against 15.89 and 18.20 for the previous two weeks.

In the 28 greater towns of England and Wales with an estimated population of 9,398,275, for the week ending July 7th, the death-rate was 15.0. Deaths reported 2,710: infants under one year of age 689; diarrhœa 94, whooping-cough 63, diphtheria 53, measles 32, scarlet fever 25, fevers 21, small-pox (Preston seven, Bradford one,) eight.

The death-rates ranged from 9.1 in Brighton to 22.2 in Preston: Birkenhead 11.5; Birmingham 15.4; Bradford 13.4; Hull 13.7; Leeds 15.3; Leicester 11.4; Liverpool 15.8: London 14.8; Manchester 21.0; Nottingham 9.9; Oldham 17.4; Sheffield 14.3; Sunderland 18.2.

In Edinburgh 16.9; Glasgow 18.9; Dublin 20.2.

The meteorological record for the week ending July 21, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.		Velocity of Wind.		State of Weather.[1]		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 27, 1888, TO AUGUST 3, 1888.

MAGRUDER, L. L., surgeon United States Army. Is granted one month leave of absence to take effect on or about August 13, 1888. Paragraph 11, S. O. 171, A. G. O., July 25, 1888.

VICKERY, RICHARD S., major and surgeon, United States Army. Leave of absence extended two months. S. O. 166, A. G. O., July 19, 1888.

WAITE, ROBERT H., surgeon United States Army. Is relieved from duty with Battalion 1st Infantry, at Santa Barbara, Cal., and will proceed to Angel Island, Cal., on public business; on the completion of which he will stand relieved from duty in this department. Paragraph 4, S. O. 43, Headquarters Department of California, July 17, 1888.

MUNN, CURTIS E., assistant surgeon United States Army. Will proceed to Santa Barbara, Cal., and report to commanding officer of the 1st Battalion of Infantry, for duty. Paragraph 3, S. O. 43, Headquarters Department of California, July 17, 1888.

JOHNSON, HENRY, captain and medical store-keeper United States Army. Leave of absence granted for one month and fourteen days, from August 1, 1888. S. O. 170, Headquarters of the Army, A. G. O., July 24, 1888.

JARVIS, N. S., assistant surgeon United States Army. Is granted one month leave of absence on surgeon's certificate of disability, with permission to go beyond the limits of the Department. By Paragraph 1, S. O. 90, Headquarters Department of the Missouri.

COCHRAN, JOHN J., assistant surgeon United States Army. Will proceed to Benicia Barracks, Cal., on public duty, on completion of which he will return to these Headquarters. Paragraph 1, S. O. 44, Headquarters Department of California. San Francisco, Cal., July 20, 1888.

ROBERTSON, REUBEN L, assistant surgeon United States Army. Is relieved from duty at Fort Keogh, Mont. Ty., and will report to the commanding officer at Fort Buford, Dak., for duty at that post, and by letter to the commanding general, Department of Dakota, S. O. 167, A.G. O., July 20, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING JULY 28, 1888.

PENROSE, THOMAS N., surgeon. Detached from Navy Yard, Boston.

PARKER, J. B., surgeon. Ordered to the Navy Yard, Boston.

MCCORMICK, ALBERT MCD. Commissioned assistant surgeon in the Navy.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JULY 28, 1888.

MURRAY, R. D., surgeon. To proceed to Manatee, Fla., on special duty. July 21, 1888.

WASDIN, EUGENE, passed assistant surgeon. To proceed to Key West, Fla., for temporary duty. July 21, 1888.

FATTIC, J. B., assistant surgeon. To proceed to Memphis, Tenn., for temporary duty. July 28, 1888.

WOODWARD, R. M., assistant surgeon. When relieved, to proceed to Boston, Mass., for duty. July 24, 1888.

GOODWIN, H. T., assistant surgeon. When relieved, to proceed to Cincinnati, Ohio, for duty. July 24, 1888.

GUITERAS, G. M., assistant surgeon. Appointed an assistant surgeon July 23, 1888. Assigned to duty at Marine Hospital, New Orleans, La., July 24, 1888.

HUSSEY, S. H., assistant surgeon. Appointed an assistant surgeon July 23, 1888. Assigned to duty at Marine Hospital, Baltimore, Md., July 24, 1888.

CASES OF LAPAROTOMY FOR TUBERCULAR PERITONITIS.[1]

BY A. T. CABOT, A.M., M.D.
Surgeon to the Massachusetts General and to the Boston Children's Hospital.

Laparotomy for the cure of tubercular peritonitis is an operation the usefulness of which was discovered by accident, and it is one of the benefits for which we have to thank the ovariotomist.

In the year 1862, Spencer Wells, the Nestor of abdominal surgery, operating for what he believed to be an ovarian tumor, opened an encysted peritoneal effusion, and found the walls of the cavity and the surrounding peritoneum thickly studded with tubercles. Recognizing his mistake, he closed the abdomen after thoroughly removing the fluid, and the patient not only recovered from the operation, but was speedily relieved of all symptoms and evidences of tuberculosis, and lived for more than twenty years afterwards. The significance of this success was not understood at the time, but gradually there accumulated a series of similar accidental cases scattered through the literature of ovariotomy which finally arrested the attention of abdominal surgeons, and seemed to show that peritoneal tuberculosis is often, if not usually, a local process which, if taken in time, may frequently be arrested by an incision into the abdomen.

Besides the array of patients that demonstrate this fact clinically, Hirschfeld has observed a case thus operated upon which subsequently came to autopsy, and it was found that the tubercles had disappeared from the serous coat of the bowels where they had been seen to exist at the previous operation.

The following cases are reported as a contribution to the statistics of this operation, and the second of the two is interesting as being one of the first cases in which the diagnosis of tuberculosis was made before operation, and the incision was made in the hope of bringing the tuberculous process to a standstill. This child was the youngest patient upon whom the operation has as yet been done.

Case I. Minnie B., colored, aged sixteen. Entered the Massachusetts General Hospital June 15, 1886. She was well as far as she knew till two weeks before entrance, when she noticed swelling of the legs. One week later the abdomen was perceptibly swollen, and she began to be troubled with dyspnœa. Examination of the heart showed a soft systolic souffle at the apex. The urine examination was negative.

June 16th. The patient complained of much pain in the upper part of the abdomen, shooting up into the chest. She was greatly prostrated. From this time the abdomen swelled rapidly, and soon became very tense.

June 21st (three weeks from the appearance of the first symptoms of ill-health), Dr. W. L. Richardson tapped her to relieve the distension, and drew off something over three quarts of dark yellow fluid. At this time the abdomen when emptied was felt to contain some ill-defined irregular lumps. After this tapping a circumscribed tumor slowly made its appearance in the middle line below the umbilicus.

September 8th. I saw her for the first time in consultation with Dr. F. C. Shattuck, and found a unilocular collection of fluid rising out of the pelvic cavity into the abdomen as high as the umbilicus. Vaginal examination showed the pelvis pretty well filled by a mass pressing down into the posterior culde-sac, in which fluctuation could not be well made out.

Dr. Shattuck, from previous examinations, had thought the case to be one of tubercular peritonitis, but the development of a single cystic tumor, and the absence of any hardening in any other part of the abdomen made the appearance of things strongly suggest an ovarian cyst which had, in its early growth, been accompanied by ascites. I inclined to this view, and advised an exploratory operation.

The patient was transferred to my ward, and on September 17th, I operated with the usual incision midway between the pubes and umbilicus. It was found impossible to separate the peritoneum from the cyst wall, and an opening was made into the sac. The wall was fully three-quarters of an inch in thickness, and was found to be the greatly thickened peritoneum. A free opening was made, and three quarts of fluid and of a jelly-like material were removed. The cyst did not collapse when emptied, as its walls were everywhere attached to the surrounding parietes. The cavity was packed with iodoform gauze, and a tube was introduced into Douglas's pouch. Over this an antiseptic dressing was applied.

A considerable portion of the cyst wall which was removed was sent to Dr. W. W. Gannett for examination, and he found it filled with typical miliary tubercles.

The subsequent history of this case was that she promptly recovered from the operation, and slowly but surely gained health and strength. The interior of the sac suppurated, and for a long time the discharge was considerable. It slowly diminished, however, and on March 23, 1887 (six months after the operation), she left the hospital with still a discharging sinus, but otherwise in good condition. She went to friends in the Southern States, and was lost sight of.

Case II. Clara T., three years old, entered the Children's Hospital July 25, 1887. There was no history of syphilis. Her mother died of phthisis when she was ten months old. A maternal aunt had also died of the same disease. The child was in the hospital in the winter of 1886 for debility from want of care since her mother's death, and was discharged well in six or eight weeks.

Six months before her second appearance at the hospital a diffused swelling of the abdomen was noticed, which increased slowly but steadily. Her bowels had been loose for about five months, and she had been troubled somewhat with otorrhœa and coryza. At the time of her entrance she was considerably emaciated.

Dr. H. C. Haven, in whose wards she then was, made a careful examination of the heart and lungs, with negative result. The urine showed nothing abnormal. The abdomen was much distended and very tense. It was dull upon percussion everywhere except over the highest point, where it was tympanitic. The cutaneous veins were not distended, and the liver was not appreciably enlarged. The circumference at the umbilicus was at this time twenty-three and one-half inches.

August 5th. I saw her with Dr. Haven, and coincided with his diagnosis of a probably tubercular

[1] Read before the Surgical Section of the Suffolk District Medical Society, March 7, 1888.

peritonitis. We tapped her and withdrew three pints of greenish-yellow fluid, thereby reducing her girth to twenty-one and one-half inches.

The fluid slowly reaccumulated, and on September 21st her abdomen measured twenty-four and one-half inches. Dr. T. M. Rotch now tapped her again, and withdrew three and a half pints of greenish and ropy fluid.

This time the reaccumulation was even more rapid than before, and it seemed proper to resort to the more decided measure of an incision into the peritoneal cavity.

She was, therefore, transferred to my care, and on October 15th I opened the abdomen by an incision one inch and a half in length. The confirmation of the diagnosis was immediate and complete. Every portion of the peritoneum which could be reached was thickly studded with little round firm bodies projecting everywhere from its surface, and often hanging off with a slender pedicle. So abundant were these that the finger, when introduced into the abdomen, felt as if it were lying in a bag of small shot. The fluid, amounting to a little more than two quarts, was removed as thoroughly as possible, and a small bit of omentum with several tubercles attached was removed for examination. A little piece of rubber drainage-tube was introduced through the abdominal wall to provide for the escape of any fluid that might form in the next day or two, and the wound was closed about it. An antiseptic dressing was applied.

At the end of twenty-four hours it was found that no fluid was escaping through the tube, although a little leaked away around it. The tube was removed. Everything went well, and at the end of ten days the stitches were all removed, the wound being closed down to a granulating spot where the tube had lain.

November 3d (sixteen days after the operation), the child developed a sharp attack of bronchitis, which ran into broncho-pneumonia, and for a number of days she was dangerously ill, but slowly she got better, and in the course of the next month the lungs entirely cleared up, relieving us of the fear that tuberculosis might be developing itself there.

November 22d the wound broke down slightly, and presently discharged a small silk ligature, the one we had tied about the pedicle of the bit of omentum that was removed.

From this time the child steadily improved in flesh and strength, and regained the ruddy appearance of a healthy girl of her age. There was never any tendency to a return of the ascites, nor was there any hardness or tenderness to be detected in the abdomen.

The question as to how a simple incision into a peritoneal cavity filled with ascitic fluid, and studded with tubercles, works an arrest and apparent disappearance of the tubercular process is one of the hitherto unexplained enigmas of surgery. The observed facts are as yet too few to serve as the basis of any well-grounded theory on the subject.

Hirschfeld's observations show that the tubercles actually disappear from surfaces where they had been shown to exist, but we have not yet had the opportunity of sufficiently examining the conditions which accompany the cure of tubercular peritonitis.

In our endeavor to understand it, however, we should bear in mind certain characteristics of the tubercular process which are well observed in other places. In local tuberculosis of the joints or bones we know that in certain cases the disease undergoes a spontaneous cure, or, at least, becomes quiescent, and does not again appear during the life of the individual. This process of retrogression is greatly favored by securing for the diseased part absolute rest and freedom from irritation, and by improving the nutrition of the patient through general measures, hygienic and medicinal.

When we get an opportunity to examine a joint which has suffered from tuberculosis and has recovered, we find the parts thickened and changed into fibrous tissue, with here and there cheesy or calcareous masses surrounded by a firm capsule. The process which has brought the tuberculosis to a standstill is analogous to that which we are familiar with around a cancerous growth. In each case the connective tissue about the morbid new growth is stimulated to increased activity, as is shown by the zone of new cells which surrounds both the tubercle and the cancer. These cells may finally develop into connective tissue fibres which surround and encapsulate the morbid new formation, and this fibrous tissue may finally, by its contraction, so press upon and interfere with the nutrition of the new growth as to lead to its death and disappearance by a process of fatty degeneration. This is the course of events so commonly observed in the scirrhous or hardening cancers, and also well illustrated in a tuberculous process developing in the midst of connective tissue.

It rarely happens that the vigorous growth of a cancer is definitively arrested by this effort of the surrounding tissues; for while it is held in check in one direction, it extends itself in many others, and breaks through the comparatively feeble barriers thus opposed to its progress. In tuberculosis, however, we have a process of much less vitality, and which, occurring in younger subjects, is often successfully hemmed in and destroyed by the healthy tissues about it.

Now, in the case of a tuberculosis of a serous membrane, the morbid growth takes place under somewhat different conditions, especially when an effusion has distended the cavity. Here the tubercles form upon a surface from which they project. They are in contact with the healthy tissues on but one side. On the other they are bathed in a serous fluid which favors rather than hinders their growth. They often become pediculated, and hang off into the serum, almost detaching themselves from the membrane in which they originated. Under these circumstances it is easily seen that the tissues have but little chance to surround the tubercles by a zone of fibrous tissue, and so bring about their destruction.

Turning now to a consideration of the conditions under which a cure has been brought about by surgical interference, we find reports of cases in which simple tapping and drawing off the fluid has been followed by an apparent arrest of the disease. These cases are, however, very exceptional, and leave us in some doubt as to the correctness of the diagnosis. The more radical procedure of making an opening into the abdomen and thoroughly evacuating the ascitic fluid has been followed by a very much greater degree of success.

Some operators have sprinkled the abdominal cavity with iodoform; others have washed it out with corrosive sublimate solution, or with simple water; others again have used carbolic acid in an antiseptic

wash. All of these measures have been followed by about the same degree of success, and we are led to conclude that the special method of operating or of subsequent treatment of the wound or peritoneum is of no special importance, but that the one thing which is of importance is the thorough evacuation of the fluid, and it does not much matter how it is done, provided it is complete.

The difficulty of entirely removing an ascitic fluid through a canula seems sufficient to explain the rare occurrence of a cure after the imperfect evacuation of a simple tapping.

Dr. Van de Warker, in an interesting article in the *American Journal of Obstetrics* for September, 1887, points out two ways in which the accumulation of ascitic fluid may, perhaps, act to intensify the morbid process: first, through its mechanical irritation by pressure, or by some unexplained irritating quality in its constituents; and, secondly, by acting as a medium for the propagation and distribution of the tubercular germs.

Granting the effect that the effusion may have in assisting the spread of the process in either or both of these ways, we can see how the removal of the fluid might somewhat hinder the extension of the disease, but we still have to explain the effect that removing the effusion has in causing an actual disappearance of tubercles already existing.

Upon this point Dr. Van de Warker says: "The irritated peritoneum is given a rest and allows of a process that belongs *per se* to tuberculosis, namely, the thickening and induration of the surfaces — an incapsulation — and which, Hegar suggests, may be a stage in spontaneous cure."

It seems to me that this suggestion of Hegar's is of the greatest interest, and that it is probable that the rest afforded to the peritoneum is of importance in allowing it to set up its process of induration, and so to resist the advance of the tubercles, but we may go a step farther and appreciate another effect of the removal of the effusion which must, I think, play a very great part in bringing about the disappearance of the tubercular process.

As has been said, the tubercles upon the peritoneum are free upon one side, and frequently even hang off from the surface so as to be almost detached from it. Now, under these circumstances, the tissues have no opportunity to surround them with a zone of young cells, which shall become fibres, and so shut them in, encapsulate and destroy them. This condition exists as long as the abdomen is filled with fluid and the peritonial surfaces are separated.

When, however, the fluid is wholly removed, and the peritoneal surfaces fall together and acquire adhesions, the tubercles are then shut in between the coils of intestine, the omentum and the abdominal wall. They are thus surrounded by tissues in a high degree of activity, which can now throw around them the limiting zone of young cells, and eventually fibrous tissue, which, if the tubercular process is not too far advanced, may effectually resist it, and cause it to retrograde.

Lastly, in regard to the method of operating. As has been said, the simple evacuation of the fluid is all that we have to accomplish, and the wound may then be closed as after any laparotomy.

In both of my cases I used a drainage-tube, but I shall not do so again. According to reported observations, even so large and thick-walled a cavity as existed in my first case may be safely sewed up, with good hopes of arresting the tubercular process, and by discarding the drainage-tube we avoid the formation of a fistula with the long suppuration, which was a troublesome feature in this case.

In the discussion which followed the reading of the above paper, DR. ROTCH made the following remarks regarding Dr. Cabot's second case:

On taking charge of the medical wards of the hospital in September, I found in one of the beds this child, three years old, who has been presented to the inspection of the Society to-night, apparently well, and with no remains of the disease from which she was then suffering.

On physical examination, I could detect nothing abnormal in the chest: the abdomen was found to be uniformly distended with fluid. The child was losing in weight and appetite. There seemed to be no doubt but that it was a case of tubercular peritonitis; and, after observing the child for several days, I aspirated the abdomen, but did not succeed in completely emptying the abdominal cavity. The fluid quickly reaccumulated, and, from my experience with similar cases, I considered that the child would gradually grow weaker and die unless some radical procedure should be adopted. I, therefore, transferred the case to Dr. Cabot for operation.

I have nothing to add to Dr. Cabot's excellent review of the subject and his practical, common-sense remarks and suggestions as to the process of repair which takes place in the cases of recovery; but I wish to bear testimony to the confidence in antiseptic surgery displayed by Dr. Cabot in operating on this young child, the youngest laparotomy, as far as I can learn, which has been done for tubercular peritonitis, and which will mark a decided era in the treatment of the disease, for it hands it over from the domain of medicine to that of surgery. Any one who will recall the usual picture of children with tubercular peritonitis as they sit in our wards, treated with various drugs according to the fancy of the attending physician, and occasionally tapped for temporary relief from urgent mechanical symptoms, — in the large majority of cases, however, only waiting for the fatal issue, — will, I think, acknowledge that a great advance has been made towards saving life, and that great credit should be given to the surgeon who accomplishes such favorable results.

We may hear of occasional cases where tapping has produced a cure, but they are exceptional, as are the cases of empyema which are at times reported as being cured by one or two aspirations, the rule being that a free incision is the alternative to a fatal issue. And since the abdominal incision, under antiseptic precautions, is being more and more proved to be a harmless procedure, we certainly should not wait for further developments when our diagnosis is once made, and in waiting run the risk of the morbid process arriving at that period of growth where no treatment will be of any avail.

If the gentlemen here present could have seen this now healthy child as it appeared in my wards, losing ground every day, looked upon by me as a hopeless case, and, as I said before, merely waiting for death, they certainly would agree with me in at least designating the operation and its result as brilliant.

THE DETECTION OF MORPHINE IN THE URINE AS A MEANS OF DIAGNOSIS.[1]

BY BENNETT F. DAVENPORT, M.D., BOSTON.

IT has continued to this day a disputed question, in spite of the many exact accounts of instances when it had been done, whether the presence of morphine could actually be determined in the animal organism, and how far it could accurately be done. There has been two opposite opinions held upon the subject. According to the one, morphia, when once absorbed into the tissues, became decomposed, and could, therefore, no longer be determined as such, while the others held that it was excreted in the urine still undecomposed.

The first method for the determination of the morphine originated with Lassaigne in 1824. He, however, was enabled to detect but traces of it in the blood of horses into whose jugular vein he had injected it in large doses. Christison, in 1831, and Taylor in 1862, sought in vain to detect morphine. Clocka, in 1866, could detect no trace of morphine in the blood of one with the opium habit. Erdman, in 1862, failed to detect morphine in the urine of several rabbits that he had poisoned with morphia. Instances of such negative results could be very numerously mentioned. They are, however, opposed by the positive results obtained by Orfila in 1839, Gscheidler in 1869, and notably by Kauzmann and Dragendorff in 1868. These last two were enabled by their method of examination to detect the presence of morphine in the urine of those who had been poisoned by it, every time, without exception. Landsberg, however, who reviewed their method, was not able to confirm their results, for he failed in the most of his cases, and Wislicenus was not more fortunate.

Burkart, who investigated this subject still later, 1882, made use of a method combining those of Dragendorff, Kauzmann, Landsberg, and Wislicenus. His results, obtained from excreted morphine and mixtures of urine and morphine of like amount, and both injected into rabbits, made it to appear probable that the uncertain results obtained by the last two were best to be explained by the theory that either but a part of the morphine absorbed was excreted unchanged, or else that, while it was not changed as to its character, its intensity of action as a poison was. He in many cases found that none of the alkaloid was excreted unchanged into the urine. In other cases but a trace, all the rest being so changed as to prevent the usual modes of detection.

Later, Marmé, who was confirmed by Warnecke, showed that some morphine did pass unchanged into the urine, and he later devised elaborate methods for demonstrating the presence of morphine in the various fluids and tissues of the body under all possible circumstances. In 1884, Dragendorff, assisted by Schneider, published his investigations concerning the correctness of Burkart's morphine decomposition product being contained in the urine, and as to how large a portion of the morphine consumed by one having the opium habit was again excreted in the urine.

Dragendorff's method of separating morphine from the urine was as follows: The urine, without any concentration, is made slightly acid by a few drops of dilute sulphuric acid, and then shaken out with one-fifth one-third its volume of amylic alcohol during five minutes. It is then set one side to separate as clear as possible. This way of shaking out with fresh amylic alcohol is repeated four to five times to remove as much of the urea as possible. The fluid is then made slightly alkaline with ammonia, and the morphine itself separated by being shaken out in hot amylic alcohol. This solution in the alcohol must be most carefully freed from any of the adhering urine by settling and filtration, so that upon its evaporation no droplets of watery fluid may be formed. Repeated washings of the alcoholic morphine with water cannot be used when there is but a trace of morphine present. By his method, he claims that 0.01 grm. morphine in 300 cc. urine can be well recovered.

Of the reactions for the determining of the presence of morphine in this urine extraction, the Fröhde, that is, concent. sulphuric acid containing molybdium is the best, but it is not alone sufficient, as other alkaloidal substances give a similar red-violet coloration. Dragendorff denies the assertion of Burkart that pure morphine must give a blue-violet color with this reagent. Although pure morphine muriate does give the blue-violet color, yet this same salt, when recovered as a free alkaloid by the Dragendorff method out of a urine, will give a red-violet color. Therefore, Burkart, when from the urine of a morphine-eater he obtained an alkaloid that gave a blue-violet with Fröhde's reagent, ought to have doubted its being pure morphine, but he ought to have considered it as an unaltered morphine when it gave the red-violet reaction.

To Burkart's claim that the red-violet coloring material which he obtained from the urine of a morphine-eater was neither a decomposition product nor a urine compound of morphine, but an independent constituent of urine, and to his argument in support of this that he had obtained a beautiful red-violet color from the urine of a morphine-eater who had been taking it for ten days, Dragendorff replies that he has never been able to obtain from the urine of one who had not been taking morphine a constituent which either had an alkaloidal reaction or shared in the Fröhde's reaction of morphine. The blue reaction of iron chloride with morphine is of importance because that it separates morphine from all the other alkaloids which give a reaction with Fröhde's reagent similar to morphine. It is well known that the iron test requires certain special conditions: considerable purity of alkaloid, no excess of acid or reagent, and the alkaloid to be present in considerable quantity.

The experiments of Schneider confirmed the opinion of Hangmann and Marmé, that with doses of from 0.01 to 0.03 grm., morphine taken either by the mouth or under the skin, it could with certainty be discovered in the urine. His cases were those of an old woman, who had for fifteen years been a morphine-eater. At this time her doses were 0.24 to 0.36 acetate daily by the mouth. A student who was taking 0.48 grm. muriate daily, and a woman who was taking 0.024 grm. of the same daily subcutaneously. In all these cases positive results were obtained by the last-mentioned; that is, Fröhde's, the iron chloride, and also by the Huseman's reaction. A further evidence that the urine, after the use of morphine, contained that actual alkaloid, is the experiment of Burkart, who obtained from the twenty-four hours' urine of one using 1.3 to 1.55 grms. of morphine

[1] Read before the Boston Society for Medical Observation, May 7, 1888.

muriate a day an alkaloid which, injected subcutaneously into dogs and rabbits, developed the symptoms of severe morphine-poisoning. It has now been determined that from the urine of men and animals who have taken morphine either by the mouth or subcutaneously, an alkaloid can be obtained which has a crystalline form, a solubility of chemical reactions, and a physiological working like to morphine. The question whether it is actually unaltered morphine, or a decomposition product of the same, can only be answered when it has been obtained in a sufficient quantity and purity to make an ultimate elemental analysis of it possible, and for the determination of its other properties.

Among others, Scheibe and Eliassor, in 1882, have each proposed, as they claim, improvements in the Dragendorff method of separation, the former using an ethereal alcohol as his last solvent, and the latter acetic ether, with a previous precipitation of some of the constituents of the urine with lead acetate. In this last method, an intense gray or green-blue color is sometimes produced by the Fröhde's reagent, which he held to be a decomposition product of the morphine. Notta and Lugan have proposed a method similar to that of Eliassor, and he finds that the kidneys, when in their normal condition, excrete a portion of the morphine unchanged. Oxydi morphine is the name which Marmé and others have given to the form of morphine formed, as he claims, in the system in cases of chronic morphine-poisoning, and its reactions differ from morphine in certain particulars with the more generally used morphine reagents, all which he has set forth in his article, published in 1885, with most minute details. In this connection, it is of interest to note that a simple water solution of morphine seems to change partially in time into apomorphia, thus explaining, may be, the nausea, said to be more marked when such an old solution has been used. Furthermore, the possible influence of ptomaines upon the chemical reactions of morphine are to be considered in a medico-legal case where the sample of the alkaloid to be identified is obtained from the liver, for instance, and also from the urine after death. According to the researches of Hilger and Tamba, which were published in 1886, morphine in presence of ptomaines can be identified through its sugar and sulphuric acid reactions, whereby the violet color is sharply induced; further, also, by its like reaction with concentrated sulphuric acid on evaporation in the water-bath, with the later addition of hydrochloric acid, etc. Iodic acid may not be reduced by the morphine itself in the presence of more than a trace of ptomaine, for many ptomaines have of themselves a strong reducing action. All the other usual tests for morphine are not serviceable in the presence of ptomaines. They found, however, that boiling ether dissolved out the ptomaines from slightly acid solutions, especially if it had been evaporated upon gypsum. In this the morphine would remain undissolved. Also that in ethereal solutions of alkaloids and ptomaines, the addition of ether saturated with oxalic acid would, on long standing, precipitate out the alkaloid as a crystalline oxalate, while the ptomaine remained wholly in solution. Furthermore, Bouchard has determined that a healthy adult man produces upon an average in twenty-four hours enough urine poison to cause death in an animal weighing 46.5 % as much as himself, if it be injected into its circulation.

Dr. Harley, in his "Old Vegetable Neurotics," says that during the action of opium, so long as any hypnotic and anæsthetic influence remain, the excretions are retarded; but when simply hypnotic and stimulant, or when the person becomes habituated to its use, the secretions and excretions are abundant and free. Dr. Anstie, in his "Stimulants and Narcotics," conjectures that in fatal cases there may be a condition of hasty and profuse shedding of the epithelial cells, such as occurs in some forms of fever, and which is usually associated with diminished secretion. Dr. Edes, in his "Therapeutic Handbook," mentions the fact that in severe opium-poisoning the urine may contain albumen and casts. Professor Huseman, in his "Toxikologie," however, claims that there is simply a retention of urine in the bladder, due to diminished sensibility, rather than any diminished secretion, for the bladder is usually found to be distended in fatal cases; that a desire to void it has usually been felt, which could not be satisfied. Headland, in his "Action of Medicines," also asserts that opium scarcely, if at all, lessens the secretion of the urine.

The experiments of Dragendorff and Kaufman showed the following: In a cat which received into its stomach a dose of 0.183 grm. morph. sulph. dissolved in water, the urine passed ten minutes later did not yet contain any morphine. In a kitten, two hours after a subcutaneous injection of 0.03 grm., it was found in abundance. In a medium-size dog, four and a half hours after a stomach dose of 0.31, it was found in large quantities. After an injection of 0.135 in the thigh of a cat, the elimination was not yet completed after thirty-six hours. In a cat which received 0.03 in a gelatine capsule, it was fully complete in fifty-two hours. A large shepherd dog, after several large daily doses in capsules, in fifty-four hours after its last dose of 2.007, had no longer any in its urine. Later, after a dose of 2.48, it still had some at the end of eighty-four hours, but not at the end of ninety-four. A medium-size dog taking 0.31 in solution in stomach had it still in the urine at the end of forty hours, but that passed three times during the next twelve hours had none. The same dog, after a like dose, but subcutaneous, had no alkaloid in the urine at the end of fifty hours. A man who took one-sixth grm. had it in his urine during twelve hours, but not after that. Dr. Dragendorff found that the Fröhde's reagent would show its reaction in the presence of only 0.000,005 grm. alkaloid, the Huseman test with only 0.000,01, while the iron chloride test required not less than one part morphine in five thousand of the solution tested.

The possibility of being able to detect with certainty the presence of morphine in the urine of one who has taken the alkaloid in but the ordinary medicinal dose is of great practical utility in the detection of the opium habit, since, as is well known, the word of those addicted is not well to be relied upon in this particular; also in hospital practice for the detection of relapses in those who have been under treatment, but have so far recovered as to be trusted with some outside liberty.

I have recently had occasion to examine five samples of urine for Dr. Goldsmith, the Superintendent of the Butler Hospital at Providence. Two were from patients who were thought to be cured, and had been allowed to go outside before their final discharge. As morphine was found in neither of them, they were, therefore, discharged from the hospital. Another

was from a case which had been known to take one-half to one and one-half grains morphine daily for some time, but had omitted it for two days, had then taken one-half grain. Beginning thirty-six hours after this last dose, the next twenty-four hours' urine gave no reaction for morphine. The next two samples were from patients taking one-eighth of a grain three times daily. In each of these morphine was found. It is, of course, needless to say that the probability of the presence or absence of morphine was unknown before it was reported upon. These are simply examples of within what limits of time and dose I have been able to detect its presence in the urine secreted.

CLINICAL NOTES OF A CASE OF PERITYPHLITIS; LAPAROTOMY THIRTY-TWO HOURS AFTER THE BEGINNING OF THE ATTACK; DEATH ON THE THIRTY-EIGHTH DAY.[1]

BY S. E. WYMAN, M.D. CAMBRIDGE, MASS.

IT has seemed to me to be desirable to place upon record the following notes, as a contribution to the study of operative interference in cases of perityphlitis.

It need not be said that it is a matter of deep regret that the result should have been unfavorable, when everything seemed so auspicious at the time of the operation, which was not deferred until the patient's strength had been exhausted by protracted suffering. I have never answered to my own satisfaction the question, "Why must he have died?"

July 21, 1887. C. M. R., male, a native American, has never been strong; is fourteen years old. From the second to the eighth day of life "he vomited black stuff, as nearly like blood as could be." He began to grow fleshy when nine years old, and is now a pale, anæmic, fat boy, weighing at present 145 pounds. He has never cared to do as much running as his schoolfellows did; has suffered considerably from indigestion, and, during the past two years, has had several attacks very similar to the present one, having had three within the past four weeks. Yesterday ate watermelon and blackberries, and, at three o'clock, morning, was awakened with severe abdominal pain in umbilical and right iliac region. Present attack of pain very severe, causing him to scream and toss about; was treated by his parents by hot local applications until 7 A. M., at which time I saw him and obtained his history. The patient has vomited twice, small quantity, liquid contents of the stomach. Expression is anxious; abdominal tenderness great, especially in umbilical and right iliac region. No tympanites. Considerable dulness on percussion in right iliac region. Decubitus dorsal, with knees drawn up. Pulse, 96, temperature 98.4° (mouth). He was ordered morphia with belladonna sufficient to control pain, hot applications to the bowels, and liquid diet. Was seen at 10.45 A. M., when it was learned that the abdominal pain was greater and more general, and tympanites had begun to show itself. Has vomited once. Peristalsis not so active, and abdominal walls kept motionless during respiration. Pulse 90, temperature 98.6°. 3.15 P. M. Has been kept quiet, with almost no complaint of pain, and much less tenderness, by the morphia. His face is flushed. Pulse, 90–120, temperature 100° (mouth). Pupils not contracted. 7.12 P. M. Hourly administration of morphia has kept him free from pain and vomiting. Urine, scanty in amount, passed with some difficulty. No change in local symptoms. He has been inclined all day to lie on his right side, and twice has been found sleeping in this position, although he thinks it causes more tenderness in right iliac region. Pulse, 112, temperature, 100.8°.

July 22; 6.45 A. M. Passed a fairly comfortable night, and complained less of pain. There has been no vomiting; no dejection; urine rather scanty; less abdominal tenderness generally, as well as in right iliac fossa. Pulse 108, temperature 99.6° (mouth). 10.45 A. M. Was seen in consultation by Drs. Marcy and Nelson, who concurred in the diagnosis, and advised operative interference. Ether was administered and laparotomy was performed by Dr. H. O. Marcy, whose notes I take the liberty of copying. The operation lasted more than ninety minutes.

"When under ether there was to be clearly outlined under the thick abdominal wall a firm resisting thickening in the right iliac quarter. An incision was made five inches long, through an inch or more of fat, and the muscles divided. The peritoneum was adherent over a space of about two inches to the omentum and surrounding parts, and the adhesions were separated with some difficulty and hæmorrhage. The head of the colon, with the appendix, was imbedded in a thick, organized mass, and firmly adherent to the abdominal wall. The adhesions were broken up with much difficulty, and the hæmorrhage was quite troublesome. The bleeding, adherent omentum was sewed through by the double stitch with catgut, and excised. The intestine above and below was found healthy. It was clearly determined that there was no suppuration about the appendix. The plastic mass was too firmly adherent and vascular to be safely removed except a small portion between the head of the colon and the abdominal wall. The bleeding points were secured and the wound closed, the peritoneum with a fine continuous animal suture, and the external wound under the mercuric bichloride solution irrigation."

He came out of his ether well, vomited at 2.30 P.M. Pulse, 132, temperature 98.4° (ax.).

℞ Is to have morphia by suppository, p. r. n.

9.30 P. M. Has vomited once or twice, and been made comfortable by morphia suppositories. Is fed by enemata of

Murdock's Liquid Food	℥ ss.
Whiskey	℥ ss.
Water, q. s.	once in four hours.

Pulse 126–133, temperature 98.4° (ax.), respiration 18. No urine passed.

July 23; 7 A. M. Good night. Urine passed twice. Moderate amount of morphia given. Tongue moist and clean. Pulse 128, regular, temperature 98.4°, respiration 18. 9.45 P. M. Has vomited four times. Urine passed once. Has complained of soreness in region of wound. No pain. Has been very thirsty. Pulse 126, temperature 101° (m.), respiration 20.

July 24th; 7.30 A. M. Required morphia once in three hours. Vomited three times during night. Passed quite a large amount of urine. Flatus per anum first time this morning. Decubitus dorsal, knees erect in the form of a tent. Hands and arms over his head. Pulse 120, temperature 99.2°, respiration 20.

[1] Read before the Middlesex South District Medical Society, January 18, 1888.

3.30 P. M. Has vomited four times. Great thirst. Little complaint of pain. Passes much flatus. Has begun to take soda water ʒii at a time. Seen by Dr. Marcy at 4.30 P. M. The dressing of the wound was removed down to the protective. Wound looks well. No redness. No discoloration. The veins at one and a half and two inches distant from the edges seem more prominent than elsewhere. No tenderness on moderate pressure in the vicinity of the wound.

℞ Seidlitz powder . . . . . one-eighth, hourly.

9.30 P. M. Desire for a stool, and was on bed-pan at visit without accomplishing anything.

July 25th; fifth day; 7 A. M. Comfortable night. More sleep. Several ineffectual attempts at a stool. Flatus passed freely. Pulse 113–116, temperature 99.2°. 9.30 P. M. Has taken a small quantity of ice cream three times; vomited the last. Pulse 114, temperature 100°, respiration 18.

July 26th; sixth day; 7 A. M. Excellent night's sleep. Vomited once. Pulse 98, respiration 16, temperature 99°. 9.30 P. M. Has had a comfortable day. Vomited once. Pulse 95, respiration 18, temperature 99°.

July 27th; seventh day. Slept well.

℞ Elaterii pil., one-thirtieth grain once in two hours.

Vomited twice. Complains of fulness in the whole alimentary track. Pulse 90, respiration 16, temperature 98.4°. Afternoon. Moves from side to side as if in health. No dejection. Vomited four times. Less discomfort in every way. Has required less morphia. Pulse 88, respiration 16, temperature 98.4°.

July 28th; eighth day; 7 A. M. Good night's sleep. Vomited once. Face flushed. Pulse 90, respiration 18, temperature 99°. Afternoon. Pill elaterii has been increased to gr. $\frac{1}{15}$ without procuring any stool. Dr. Marcy saw him this afternoon, and removed suture from the external wound, whose edges, with the exception of a short space at the inner and lower angle, were firmly united. Iodoform with wool externally. Pulse 105, respiration 16, temperature 99.5°.

July 29th; ninth day; 10 A. M. Vomited five times. No dejection. Two enemata of soap suds were returned discolored by Murdock's food. Pulse 103, temperature, 98.4°. Afternoon. No dejection. Pulse 104, temperature 98.4°.

July 30th; tenth day; 1.30 P. M. Pulse 66, temperature 98.4. 7.30 P. M. Pulse 78, temperature 98.4°. Vomited once.

July 31st; eleventh day; morning. Slept well. No dejection. Vomited once. Has taken spoonful doses of beef tea by mouth. Bowels flat. No pain. No tenderness. Pulse 76, temperature 99.6°. 5 P. M. Comfortable day. Enjoys small doses of blanc mange with milk and sugar by mouth. Vomited three times. Slight fæcal dejection after enema. Pulse 90, temperature 99.2°.

August 1st; twelfth day; morning. Excellent night's sleep, without any suppository. No pain. No vomiting. Pulse 78, temperature 98.2°. Afternoon. Comfortable. Had a large, well-formed, natural dejection at noon. Pulse 72, temperature 99°.

August 2d; thirteenth day; morning. Good night's sleep, without pain or vomiting. Has eaten some blanc mange and a little soft-boiled egg. Natural dejection. Pulse 84, temperature 98.6°. Afternoon. Vomited four times contents of stomach. Pulse 84, temperature 98.4°.

August 3d; fourteenth day; morning. Good night's sleep, without pain. One suppository at 6 P. M. Pulse 70, temperature 98.3°. Afternoon. Perfectly comfortable. Dejection after enema at 2.30 P. M. Pulse 70, temperature 98.3°.

August 4th; fifteenth day. Comfortable. Wound is healing. Some thin bloody discharge flows from upper end of wound. Etherial solution of iodoform and collodion applied. Pulse 76, temperature 98.5°. Afternoon. Doing well, with the exception of a little fulness. Pulse 76, temperature 98.4°.

August 5th; sixteenth day; 10.30 A. M. Had a comfortable night's sleep. Pulse 82, temperature 98.4°. Afternoon. During the day some pain in the wound from which there has been quite a free discharge. Vomited once. Some headache. Some tympanites. Pulse 80, temperature 98.2°.

August 6th; seventeenth day; morning. Comfortable night. Complains of some fulness. Pulse 82, temperature 98°. Afternoon. Comfortable day. No pain. No dejection.

℞ Nuc. Vomic. . . . . ¼ grain.

Hungry to-night. Pulse 72, temperature 99.2°.

August 7th; eighteenth day; morning. Slept well. No pain. No vomiting. Dejection at time of visit. Ate some soft oatmeal this morning. Pulse 80, temperature 98.4°.

August 8th; nineteenth day; morning. Best day since his illness. Three dejections, one at 4 P. M. and two this morning. Has good appetite. Pulse 70, temperature 98°.

August 9th; twentieth day; morning. Perfectly comfortable, without vomiting. Dejection yesterday afternoon. Marked appetite. Pulse 68, temperature 98.4°.

August 10th; twenty-first day; morning. Comfortable. Ate lamb with broth, baked potato, bread and oatmeal. Pulse 72, temperature 98.4°.

August 11th; twenty-second day; morning. Perfectly comfortable. Two large and well-formed dejections yesterday. Wound dry. Pulse 72, temperature 98.7°.

August 12th; twenty-third day; afternoon. Comfortable. Has been sitting up in bed nearly all the morning. Pulse 80, temperature 98.2°.

August 13th; twenty-fourth day. Good night. Appetite excellent. Sitting up eating his breakfast at time of visit. Wound is practically closed. No discharge. Pulse 96, temperature 98.4°.

August 14th; twenty-fifth day; afternoon. Has had a serious set back. Sat up nearly half the afternoon. At about 4 P. M., after enema, had a good dejection, and between 10–11 P. M. and 2–3 A. M. Complained of some pain in his bowels at 10 P. M., which grew very severe, and was located in epigastric and left iliac region. Vomited at about 12 o'clock, became quiet at about 2 o'clock, but vomited again at 3 A. M. Has taken suppositories, p. r. n. Vomited again this morning. Now has only soreness in left iliac and epigastric regions. No tympanites. Peristalsis not heard. Slight coating on the tongue. Was seen by Dr. Nichols, who reported, pulse 144, temperature 100.6°. Now, pulse 136, temperature 100.4°. Urine examined and found to be normal. 5.30 P. M. Has slept some. Vomited large quantity of bilious

matter, causing him to cough, and giving pain in left iliac region. Pulse 132–137, temperature 100.8°. 9.30 P. M. Slept for some time. No pain. No vomiting. Pulse 135, temperature 100.1°.

August 15th; twenty-sixth day; morning. Slept quite well. No vomiting. No dejection. Less soreness of the bowels. Some tenderness in left iliac region; none elsewhere. No tympanites. Peristalsis heard slightly. Pulse 132, temperature 100.2°. Afternoon. Has vomited four times during day. Less tenderness. Color good. Thirst less. Abdomen moves with respiration. Pulse 132, temperature 99.8°.

August 16th; twenty-seventh day; morning. Comfortable night, without vomiting or dejection. Complains of soreness in left iliac region only when he moves. Pulse 112, temperature 98.8°. Afternoon. Comfortable, but has a full feeling. Pulse 109, temperature 99.4°.

August 17th; twenty-eighth day; morning. Comfortable. No pain. Vomited twice. Feels hungry. Face bright. Tongue clean. No tenderness. No tympanites. Pulse 99, temperature 99.1°. Afternoon. Comfortable in every way. Pulse 100, temperature 98.8°.

August 18th; twenty-ninth day; morning. Has vomited eight to ten times. Has slept since 12 o'clock. No pain. No dejection. Bowels soft. No tenderness except in right iliac fossa on deep pressure, where there is a little dulness on percussion. Pulse 99, temperature 98.6°. Afternoon. Has had an enema of epsom salts without any dejection. Looks pale and sick. Pulse 108, temperature 98.6°.

August 19th; thirtieth day; morning. No improvement. No dejection. Has vomited several times, and gagged many times without raising anything. Hiccoughed last night after vomiting. Pulse, 106, temperature 98°. Afternoon. Had a dejection after an enema at 11 A. M., and a small natural dejection at 3 P. M. Pulse 96, temperature 98.3°.

August 20th; thirty-first day; morning. Good night. Vomited a little several times. No pain. No dejection. There is still a little tumor in the right iliac region. Pulse 89, temperature 98.2°. Afternoon. Good dejection after an enema. Vomited a little. Has been sleeping for three hours.

August 23d; thirty-fourth day; morning. Has grown much worse since the 21st, when vomiting began at 11 A. M., and has continued ever since.

Owing to my own illness he was attended during the remaining days of his life by Drs. Nichols and Driver. The same symptoms continued until the close of the scene, the stomach refusing to retain any nourishment, notwithstanding all sorts of medication were tried.

He died on August 27th, the thirty-eighth day of his illness.

The autopsy was made by Drs. Driver, Whittemore and C. B. Wellington within twenty-four hours after death. Only the abdomen was opened. The peritoneum was normal everywhere, except for a little blush directly over the site of the wound made by the operation. There were a few very delicate adhesions of recent date passing from the wound to the cæcum, and the corner of the omentum bound the cæcum to a slight extent to the iliac fossa. On careful examination only a very rudimentary appendix vermiformis could be found. On opening the intestines the rectum was found empty, the sigmoid flexure well marked, having almost a supplementary curve. At the junction of the transverse and ascending colon a small amount of fæcal matter was found. In the cæcum itself a roundish mass of fæces was found about the size of a pullet's egg; otherwise, everything was normal.

REPORT OF PROGRESS IN GYNECOLOGY,

BY F. H. DAVENPORT, M.D.,
Assistant in Gynecology, Harvard Medical College.

BICHLORIDE OF MERCURY IN CIRCUMUTERINE INFLAMMATIONS.

DR. H. N. VINEBERG [1] in a paper on this subject describes that class of cases where we find on examination some loss of mobility of the uterus, and to one or other side or behind a fulness or induration which is moderately sensitive. The ovaries are found apparently enlarged and extremely tender. On one side of the uterus, usually the left, an oblong irregular mass is not infrequently detected, which is commonly looked upon as a dilated tube, but which the author thinks is as often the sigmoid flexure. Among the many complaints the most prominent and constant is pelvic pain.

As regards the diagnosis of these cases, the author does not enter into the vexed question of the pathology but calls them chronic circumuterine inflammations, the root of the affection consisting of a diffuse or circumscribed effusion of inflammatory products into the various structures surrounding the uterus.

In not a few of these cases the ordinary methods of treatment, hot water and local applications are powerless to effect improvement. The author's attention was called to the value of the bichloride, by marked improvement following its administration in an aggravated case of this character, where the attending surgeon thought he detected evidence of syphilis. The evidence for its existence was very doubtful. It was therefore tried in over thirty cases of circumuterine inflammation of this character, the details of several of which are given in full. Most of them improve faster than similar cases treated under the old method. In those cases of pain in the pelvis where the cause was doubtful, the obscurity was to a certain extent cleared up by the use of this drug, as it usually failed to relieve it, unless dependent upon inflammatory exudation.

The following mixture was usually given:

Bichloride of mercury	1 grain.
Tincture of gentian	1 ounce.
Water to three ounces.	

Dose, a teaspoonful in water, three times a day after meals.

The following are the conclusions:

(1) The use of the bichloride of mercury internally forms a valuable aid to the local treatment of circumuterine inflammations.

(2) In the doses necessary for its resolvent effect, the drug may be given for several weeks without any untoward constitutional manifestations.

(3) In some cases where the inflammatory products are deeply situated within the pelvis, the internal use of the drug seems to be more efficacious than the most approved local treatment.

(4) A short course of the drug often serves as an

[1] New York Medical Journal, January 28, 1888.

important means for the differential diagnosis of the various obscure conditions which give rise to pelvic pain.

ELECTROLYSIS AND RAPID DILATATION IN THE TREATMENT OF STERILITY AND DYSMENORRHŒA.

Try [2] claims for electricity a superiority over other methods of treating contractions of the cervical canal, which have as their prominent symptoms, sterility and dysmenorrhœa, on the following grounds: First. Its simplicity. No anæsthetics and no assistants are necessary. The treatment can be carried out at the physician's office. Second. Its safety. The electrode is made to travel the cervical canal slowly; it is arrested at the contracted portion until electrolytic action permits it to pass without the use of force. Third. The result is better. The immediate effect is favorable because the galvanic current is in itself a valuable therapeutic agent, and often suffices to cure attendant morbid states of the uterus. The ultimate result has been better in a few cases in which other methods had been previously tried. Time, however, is needed to establish this point.

The method of application is as follows: — With the patient in either the dorsal or semi-prone position, the cervix is *steadied* with a tenaculum. The direction of the cervical canal is explored with the sound. The positive electrode, consisting of a flat sponge about the size of the palm, is placed either over the fundus uteri, or over the lumbar region. The negative electrode is an insulated copper wire, with olive shaped tips of different sizes. One of these somewhat larger than the lumen of the strictured passage is passed gently into the canal, until it meets with the constriction when it is held in contact with it a few minutes until absorption removes the obstruction, and the electrode passes without forcible pressure. It is so carried slowly along the canal, and through the internal os. At the next treatment a larger olive is passed. The sittings should last from eight to fifteen or twenty minutes, and be repeated every five or seven days.

TREATMENT OF UTERINE FIBROIDS BY ELECTROLYSIS.

Dr. J. Knowsley Thornton, [3] in a letter to the *British Medical Journal*, formulates his views on this subject. In substance they are as follows: He says the discussion is premature because fibro-myomata are uncertain in their habits of growth, and retrogression, the most surprising changes taking place in the course of a few months if left to themselves; still more commonly if the patients are carefully handled as to diet, alcohol, rest at the periods, and special medicines. He thinks that nothing which has yet been published by Apostoli or his followers is inconsistent with such natural changes, aided by the effect on the nervous system of confident hope of cure. An interval of health for at least twelve months after treatment is necessary to prove a cure. He says we do not yet appreciate the dangers of the method and urges the profession to wait patiently for definite results. [As Dr. Thornton prefaces these criticisms by saying that he has never tried the method, and being a surgeon (!) does not intend to, as he thinks it may more properly be left to the obstetric physician, their value is distinctly impaired.— Rep.]

[3] British Med. Journal, March 24, 1888.

TREATMENT OF PROLAPSE OF THE UTERUS BY GYMNASTICS OF THE PELVIC MUSCLES.

Prof. F. von Preusschen [4] describes a case in which he accomplished the cure of a severe case of procidentia solely by means of the method proposed by Brandt, of Stockholm, in 1868. This method consists in the following manipulations: First, the patient is placed in the lithotomy position; the operator standing on the left side of the patient, presses both hands deeply into the lower part of the abdomen while an assistant with his finger in the vagina holds the uterus in a position of anteversion. The uterus and its apendages are seized as well as possible by the operator who forcibly pushes the organ towards the umbilicus. It is then allowed to slowly fall back. The finger of the assistant follows these movements, and by pressure on the cervix prevents the uterus from becoming retroverted. This manipulation is repeated three times in each sitting. Second, with the patient in the same position the knees and ankles are brought close together, and the patient is directed to resist an attempt to separate them. When they are separated, the reverse is done: namely, the patient tries to keep them apart, while the operator presses them together. This exercises the adductors. Third, a series of tapping movements is carried out on the lumbar and sacral regions.

The patient whose history is given had suffered from procidentia for thirty-one years. The only relief had been from the use of pessaries with external attachment. From the first day of treatment the uterus remained in the pelvis, and at the time of the report of the case there had been no prolapse for three months and a half.

The author is of the opinion that the second procedure, the exercise of the adductors is the most important factor in the treatment, though Brandt attaches but secondary importance to that and to the third. Preusschen considers the raising of the uterus of value in correcting the retroversion, and in separating adhesions between uterus and bladder, but not in strengthening the pelvic muscles. The forced movements of the thighs however, cause the whole muscular floor of the pelvis, especially the levator ani, to contract. This contraction can be made more pronounced by telling the patient at the same time to raise the buttocks from the table. In this way the lax muscles regain their tone, they restore the proper support to the cervix, and narrow the opening for the vagina in the pelvic floor.

TREATMENT OF INOPERABLE CANCER OF THE UTERUS.

J. Schramm [5] declares himself dissatisfied with any of the usual methods. These are: (1) Curetting the diseased portions, and the application of the cautery. (2) The dry method of Sänger, curetting followed by the use of iodoform gauze. (3) Alcohol treatment with or without bromine. (4) Painting the ulcerated surface with strong carbolic acid. (5) Washing out with condurango, or use of condurango salve.

Schramm recommends the injection of antiseptic fluids into the diseased tissues. He uses the following formula:

℞	Hydrarg. Bichloridi Corros.	0.25
	Natrii. Chlorati	2.50
	Aquæ	50.00

About two grammes of this is injected into the can-

[4] Centralblatt für Gyn., No. 13, 1888.
[5] Cent. für Gyn. No. 13, 1888.

cerous mass two or three times a week. The results are a clearing of the ulcerated surface, cessation of the foul discharge, and a marked retardation of the process. The general health improves, and hæmorrhages are less frequent.

CHRONIC PYELITIS.

Dr. N. Bozeman[6] describes a most interesting case of chronic pyelitis treated in an entirely novel manner. The patient, thirty-four years old, had for three years been suffering with a constantly increasing pain in the right lumbar region. This pain was variable in character, and aggravated by exercise. It was sometimes acute and sometimes dull. For two and a half years there had been blood present in the urine in varying amounts. Her general health was much depreciated, and she had lost flesh and strength. Within a few months she had had a severe illness confining her to bed for six weeks, during which she suffered from partial suppression of urine, severe paroxysms of pain, nausea, vomiting and high fever, and had found two calculi in the urine. Examination of the urine showed an acid reaction, albumen, and a sediment of blood and pus. The uterus was large, retroverted, and slightly prolapsed.

Two attempts to catheterize the ureter through the urethra failed. An opening was therefore made into the bladder, under ether, an inch and a quarter below the cervix uteri, and three-quarters of an inch to the right of the median line, sufficiently large to admit the index finger. The edges were stitched with a continuous catgut suture. A No. 8 French, olive-tipped catheter was then passed into the ureter, and entered the pelvis of the kidney without meeting any obstruction. Injections of warm water were then made, a drachm at a time being forced in, and then allowed to escape. The next day a drainage instrument devised by Dr. Bozeman, was introduced into the vagina to conduct the urine away as it came from the fistula, thus preventing its running over the mucous membrane and external genitals. This instrument is essentially a hollow, hard-rubber drain, which is shaped to fit the vagina and is connected by a soft rubber tube, with a bag or urinal attached to the thigh, near the knee. Its upper surface is grooved and perforated with a number of small openings into the hollow interior, one or more of which come in apposition with the fistula. The vaginal mucous membrane clings so closely to it, that the urine finds no other channel of escape. With this instrument all the urine was collected when the patient was sitting or standing; a little was lost when she was lying down, but not enough to cause discomfort. It also acted as a pessary to raise and antevert the uterus.

Ten days after the formation of the fistula, systematic treatment of the pyelitis was begun. Every day a flexible olive-tipped catheter was passed into the ureter, and the pelvis of the kidney was irrigated with a warm solution of bichloride of mercury, 1 to 20,000. The patient's sensations were the guide to the quantity, a dull and characteristic pain being felt when the pelvis was distended. At first the capacity of the pelvis was twenty-one drachms, but was at last reduced to five drachms, which Dr. Bozeman believes to be about normal.

Under this treatment, the pus and blood diminished and at the end of three weeks the urine was clear, and deposited no sediment. At the end of six weeks urine collected from each kidney separately, showed that the pelvis of the diseased kidney had returned to its normal condition, and treatment was discontinued. She returned in five months for the closure of the fistula, having been entirely free from pain, gained twenty-five pounds, and become strong and well. The operation was performed, and perfect union resulted. Believing that the backward displacement of the uterus might possibly have caused some obstruction to the ureter, the use of the drainage instrument was continued as an uterine support.

The author then analyzes this case, and one previously treated by the same method, as regards etiology, symptoms, course and termination, differential diagnosis and treatment in an exhaustive manner, for the details of which the reader is referred to the original article.

The following are the most important results which follow the employment of this new method of treatment:

(1) An artificial fistula furnishes an opportunity for the observation and clinical study of disease of the bladder, ureters, pelvis and kidneys, afforded by no other means. This is particularly true of catheterization of the ureters.

(2) The opportunities for treatment, especially for irrigation of the pelvis, are much greater by this method than by any other.

(3) This method of treatment of diseases of the pelvis of the kidney is much less dangerous than the grave operations of nephrotomy and nephrectomy.

(4) Intra-vaginal drainage prevents the evil consequences of incontinence of urine, and perfects the method by removing the chief objection to its employment.

A NEW METHOD OF RADICAL CURE OF RETROFLEXION.

Dr. Schücking[7] recommends for the radical treatment of non-adherent retroflexed uteri, the fixation of the anterior wall to the deepest part of the vesico-uterine peritoneal fold, in other words, the keeping the organ permanently anteflexed. This is accomplished by dilating the uterus, passing a long, curved needle, fixed to a handle, through the anterior wall near the fundus, and bringing it out through the anterior cul-de-sac, which has been pushed up as far as possible on the body of the uterus. The two ends of the suture are then tied, and the vagina packed. The histories of two cases are given. In one the suture was removed on the sixth day, the tampon omitted on the ninth, and on the fourteenth the uterus was back in its old position. The second case, in which the ligature was left in fourteen days, resulted favorably, four months later the uterus was strongly anteflexed.

USE OF THE VAGINAL TAMPON.

Dr. Emmet[8] in discussing the subject, first refers to his views on pelvic inflammations, and says that while his advocacy of the use of hot water vaginal injections was a great advance in the treatment of these troubles, yet it is not infrequently the case that no permanent benefit follows the prolonged use of this agent. This led him to study the pelvic circulation in disease, and to arrive at the conclusion that the important pathological change in cases of prolapse was traction on the

pelvic bloodvessels resulting in a varicose condition of the veins due to a loss of elasticity in the tissues surrounding them. The same condition would result from local peritonitis with adhesions.

Hot-water injections have their greatest effect in the acute stage of pelvic inflammation but when these tissue changes, and the varicose condition of the bloodvessels have occurred, they may accomplish little more than exercise a soothing effect. In these cases the use of the vaginal tampon, compressing the dilated veins, and lifting the uterus to its natural position in the pelvis, will often be followed by good results. Dr. Emmet then gives the history of an interesting illustrative case, and describes in detail his method of applying the tampon.

Clinical Memorandum.

TWO CASES OF CEREBRO-SPINAL MENINGITIS.

BY GEORGE G. SEARS, M.D.

The following two cases are of interest not only as occurring in one family at a time when cerebro-spinal meningitis occurred only in rare sporadic cases, but also because they present a number of the rarer symptoms.

On September 17, 1887, Charles W., a well-built little fellow of two years, who had always been previously healthy, was taken with headache, occasional vomiting, and sore throat. The pharynx was found to be considerably reddened, but otherwise physical examination was negative. There was constipation.

On the 20th there was considerable stiffness of the neck, and efforts to move the head caused pain. Both feet and ankles were somewhat tender and were much swollen, the swelling extending half-way to the knee and pitting on pressure. The pulse was small and rather weak. During the night he had two slight convulsions.

22d. The patient was drowsy and weaker, but otherwise his condition remained about the same. During the night he had a severe general convulsion, in which he died. The febrile movement was slight. A specimen of urine could not be obtained.

Obviously, without the evidence furnished by an autopsy, the diagnosis must be considered very doubtful, yet the record corresponds fairly well with a number of anomalous cases which are frequently reported as occurring during the prevalence of an epidemic, and offers many points of comparison with the early history of the second case, where the diagnosis seemed clear to others who saw the case with me, as well as to myself.

On the 19th, two days after Charlie was attacked, his sister Mary, eight years of age, who had been well up to this time, became slightly feverish and complained of sore throat. The pharynx was somewhat congested, but beyond that physical examination revealed nothing abnormal. The tongue was slightly coated; the pulse was full and strong.

On the 20th she began to complain a little of headache and had diarrhœa. The abdomen was distended and tympanitic, but nowhere tender.

23d. The headache has become much more severe during the past three days. It was noticed, yesterday, that the feet were somewhat swollen and œdematous, and to-day the swelling has increased. Both ankles are very red and tender, the slightest touch causing her to shriek with pain. The wrists and elbows are also painful and tender, but there is very little alteration in their appearance. She complains now for the first time of a "stiff neck," and pressure over the cervical vertebræ is extremely painful. Instead of tossing restlessly about the bed, she now lies very quiet, occasionally moaning, with the head thrown back and held rigidly.

26th. The patient has scarcely slept at all during the past three nights, owing to intense headache, in spite of bromide of potash and morphia. She lies quietly on her back, with eyes half-closed, occasionally uttering a short, sharp cry, or screaming "Papa" or "Mamma," but she replies intelligently to questions, giving her answers in quick, explosive monosyllables. There is no photophobia, the pupils are equal and react well to light. Constipation has now become the rule, and from this time on an evacuation could be obtained only with the use of cathartics. For the past day or two the amount of urine has been diminishing, and during the last twenty-four hours but five or six ounces have been passed, which was high-colored, smoky, and loaded with albumen. The skin is dry.

30th. Under the use of acetate of potash and seidlitz powders, the urine has risen to the normal amount. She complains less of headache, and the swelling of the feet has diminished and the redness of the ankles has disappeared.

During the following two weeks there was a gradual change for the worse. An erythematous eruption appeared for a day or two upon the face and chest. There was more complaint of stiffness of the neck and tenderness over the cervical spines, and the skin over the limbs became markedly hyperæsthetic. She lost greatly in weight and was more drowsy, but still answered questions with intelligence. There was slight delirium at night. The pupils were equal, but dilated, and she became somewhat deaf.

On October 21st, the temperature, which had been normal or subnormal for the four previous days, though without any amelioration of the symptoms, rose to 103.5°, and the patient became much more stupid. The right pupil is now considerably larger than the left. On the following day, the thirty-seventh day of the disease, she had a left-sided convulsion, after which she became comatose, and died a few hours later. The temperature, with the exception of the few days before death noted in the history, and the three days following the onset of the severe symptoms, when the thermometer registered 103.6°, 105°, and 104°, respectively, the morning temperature being given in each instance as the higher, rose but once to 103°. The rest of the time it varied between 100° and 102.5°, only occasionally reaching the latter point. The curve was erratic, and the morning temperatures were quite frequently the higher. The pulse-rate varied considerably from day to day without apparent cause. The greatest variation noticed on two consecutive days was from 82 to 116. No autopsy could be obtained.

The treatment consisted in local applications of ice, bromide and iodide of potash, and occasional doses of morphia. Salicylate of soda and oil of gaultheria were tried for the relief of the joint symptoms, but without apparent results.

The diarrhœa, the distended abdomen, and the general indefiniteness of the symptoms, taken in connection with the season of the year, suggested typhoid fever for a day or two, but the later progress of the disease soon settled the question. As between tubercular meningitis and cerebro-spinal fever, I based my diagnosis on a good family history, the marked stiffness of the neck and retraction of the head, the hyperæsthetic condition of the skin, the cutaneous eruption, the arthritic symptoms, and the absence on repeated examination of any evidence of tubercular deposits elsewhere.

A point of special interest was the occurrence of pharyngitis, which, with pneumonia, seems to be closely related to cerebro-spinal meningitis. In the epidemics in this country from 1811 to 1815, pharyngeal inflammations were unusually frequent, and during the epidemic in New York City in 1872, Lewis Smith says that, in his opinion, an unusually large number of cases of pharyngitis occurred. Any figures which I am able to present are too small to be of much statistical interest, but it is, at least, a striking coincidence, if accidental, that of thirty-two cases which I was called upon to treat as district physician between the 15th and 20th of September, the two cases reported above not being included, there were three cases of pneumonia and nine of inflammation of the pharynx, as against nine cases of the latter affection occurring during the rest of the month, these eighteen cases being 11.6 % of all cases treated. During the eleven months from June, 1887, to May, 1888, in which I was connected with the district, the nearest percentages to this in an average monthly clinic of over 160 new cases were furnished by the following: October with 9%, November with 8.4%, and December with 9.6% ; but as scarlatina became epidemic in the middle of October, and continued till the middle of December, many of these cases probably owed their origin to scarlatinal infection. As compared with the Septembers of the preceding four years, the difference is quite striking, the highest percentage being 3.7 in 1883.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

REGULAR meeting, Monday, May 7th, at the Medical Library, 19 Boylston Place, DR. F. H. DAVENPORT in the chair.

DR. F. W. JOHNSON read a paper on

A FEW CASES OF ABDOMINAL SECTION.[1]

DR. B. F. DAVENPORT read a paper on

THE DETECTION OF MORPHINE IN THE URINE AS A MEANS OF DIAGNOSIS.[2]

DR. J. B. AYER said that he was much interested in the paper, and that in many cases the detection of morphine in the urine would prove of much value in the diagnosis of the disease.

CREOLINE.

DR. E. O. OTIS said: Mr. Chairman: I want to call the attention of the Society to two preparations which I have been using of late in the surgeon's room at the Boston Dispensary with much satisfaction. The first is creoline, whose chemical composition, I believe, has not been determined, but it comes from the aromatic class of hydro-carbons. It is not poisonous, and combines the favorable workings of iodoform with those of corrosive sublimate. Esmarch[3] found that its anti-parasitic quality was greater than that of carbolic acid, but its disinfecting quality less. Kortüm[4] has used it with advantage in surgical cases, and also in puerperal fever. He says it cleans up wounds, diminishes suppuration, and induces a speedy cure. Neudörfer, of Vienna, uses creoline only as an antiseptic, and has found one-half to two per cent. solution efficient, using two per cent. solution for instruments and preparing the skin at the seat of operation. He says it relieves pain, checks hæmorrhage, and limits suppuration. He prepares a fresh solution each day by adding two drops of creoline to six ounces of water.

He uses it undiluted for erysipelas. It has also been used in a one-half per cent. solution to wash out the bladder, and besides being a deodorizer and hæmostatic, is said to improve the condition of the mucous membrane. I should think it might be of service as an injection for gonorrhœa, although I have never tried it. I have found it very serviceable for all the cases in which one uses an antiseptic, and especially for poultices, so that I have almost entirely discarded the ordinary flaxseed poultice. I wring out a wad of absorbent cotton in a solution of it, applying it to the suppurating wound, cover it with dry cotton, and apply a bandage. I give the patient a small bottle of the creoline, tell him to add two drops to a cup of warm water, and with this solution make a poultice in the way I have described. Pure, it is a black-looking fluid of much consistence, and with water makes a milky solution with a tarry odor. I use two solutions, one-half and two per cent. The price is about the same as that of carbolic acid.

The second preparation is

PHOTOXYLINE,

called to my attention by Dr. Louis, who assists me at the Dispensary. I use it as Von Wahl directed[5] a five per cent. solution in equal parts of ether and alcohol. It looks like collodion, but its advantages over it are said to be (*a*) its persistent, firm adhesiveness ; (*b*) its absolute impervious ness ; (*c*) its uniform compression of tissues. I use it in many minor operations and injuries. It is said to be especially suitable for plastic operations upon the face and in the neighborhood of the male genitals. Over wounds closed with sutures a thin layer of absorbent cotton saturated with it is placed, and serves as an antiseptic protective. In children, where the soaking of the dressing is not to be avoided, it is of service. It is also recommended for the sutured wounds of laparotomies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.[1]

F. B. HARRINGTON, M.D., SECRETARY.

DR. PHILIP COOMBS KNAPP read a paper on

NERVOUS AFFECTIONS FOLLOWING INJURY; "CONCUSSION OF SPINE." "RAILWAY SPINE." "RAILWAY BRAIN."[2]

DR. J. J. PUTNAM said: I have listened, as I am sure we all have, with the very greatest interest to Dr. Knapp's thoughtful and thorough paper, and the very few words I have to say will be mainly in confirmation of what he has already told us. In the first place I would like to say one word in regard to his reference to me in connection with the subject of hemianæsthesia which was spoken of as indicating hysteria. I certainly did not intend to make the cases out as cases of typical hysteria, in the sense in which he uses that term. I would retract that statement if I made it. The hysterical state is the expression I would use and one could hardly avoid using that term, for very lack of a better.

It certainly seems to me unfortunate that most of these cases are of that class where the medical man is under a good deal of social or moral pressure to consider other things besides his medical duty, and must almost of necessity do so.

I think the railroad surgeon, and even the railroad physician is not in a position to judge fairly about these cases, unless he follows them a very long time. They may recover so as to walk about and even to work, and yet they may be wholly unable to bear any considerable strain. Thus, to speak of but one case, I have in mind a patient who was injured during the war by a spent ball which struck him in the back. He also is in a condition in which it is difficult to diagnosticate any local lesion, but he has been good for nothing ever since the event.

In regard to the hemianæsthesia, it seems to me an important matter because it enables us at least often to satisfy the jury, or, at least, to satisfy ourselves, that simulation is not present; and the immediate question arises, may not a person who is not injured simulate hemianæsthesia; and the value of the sign turns upon the answer to that question. I don't think they all appreciate loss of sensation. I have seen several cases, and one in particular, where this condition was present without having been recognized by the patient at all. In one such case a burning match could be brought suddenly against the skin without his expressing pain, and yet he was walking about and doing business. It would not be easy to simulate the typical form of hemianæsthesia, I think, because that would mean too great knowledge on the part of the patient. This is especially true of the retraction of the field of vision, as tested at the blackboard on different occasions, with the patient's eye at different distances from the board. It would take an accomplished simulator to meet this test with success. I must, however, admit that I have once been deceived, and that the examination should be made with great care, and if necessary should be repeated. With regard to the line of anæsthesia on the skin, I think under most circumstances it is so accurately marked that simulation is almost out of the question; of course, not absolutely. Moreover, it seems to me that these cases do not furnish a large number of simulators. I have seen one or two men who were evidently simulating, and these were the only ones, with one exception, that I have had much reason to suspect, even afterwards.

DR. J. COLLINS WARREN. I think it is interesting to one who sees many of these cases to study the nature of the affection. The question is generally raised in court what would you call hysteria. Is it simply a functional disturbance of the nervous system, or not? Hysteria implies an impairment of the will-power rather than functional disturbance of the nerves. Such functional impairment of the nerves as accompanies this class of cases is more appropriately named nervous prostration, or neurasthenia.

The word shock has been used largely by Page ("hysteria from nervous shock"). The question arises as to what he means exactly by nervous shock. The term shock is so varied in its application in the English language; it means fright, and it means that subtle condition which accompanies injuries or severe surgical operations; it means a moral injury, so to speak, a shock to our ideas of morality. It means a great variety of things; therefore, when the term shock is used, it is a little difficult always to tell what idea the writer means to convey.

A very excellent monograph has been written by Grœningen, a Prussian military surgeon, on shock. He shows how diverse are the views of surgeons on this condition that we see after severe injuries. He thinks there is no organic change in the individual affected. He undertakes to explain it, in this way: There are four degrees of irritation which we may conceive as being produced in a sensitive nerve. First, the form which produces no appreciable change. Second, there is a severer form which produces impairment of function, like impairment of the vision or impairment of taste, impairment of hearing, etc. Frequently tasting of different strong substances, of course, will confuse and impair the sense of taste. Then comes the third degree of irritation, which will produce not only impairment of function but produce the sensation of pain; and finally, there is a fourth and one which covers all the other degrees, a severer form, which will destroy all function. It is this latter form which he conceives applied to the general nervous system which produces the grave phenomena which we recognize as the symptoms of shock. He considers shock as fatigue or exhaustion of the cord and the medulla — not so much the brain as the nervous centres in the medulla — which preside over the various functions of the body, and for the time being impair their action to such a degree that the condition is regarded as one analogous to death; in fact, shock has been described as "a momentary pause in the action of death."

Now, it has been said that we may get milder forms of irritation, and as a result of these milder forms of irritation we may have milder forms of exhaustion. So we may have an acute condition which may terminate fatally, or one from which the patient may recover, or we may have a chronic condition following, which may last for a considerable length of time, and be followed by the general symptoms which we recognize as those of neurasthenia, with perhaps local paralysis besides. Cases of railway shock may no doubt be genuine, still they are often so masked by the surroundings that it is difficult for us to draw conclusions

[1] Concluded from page 108.
[2] Reserved for publication.

from them. I do not mean to imply that such patients are malingerers, or that they are simply hysterical, but the surrounding mental and social disturbances are such as to mask the conditions greatly. I think we can study with much advantage cases which have nothing to do with litigation whatever. I have seen one or two such cases which seem to carry out the idea that there are examples of chronic exhaustion, due, perhaps, to slight injury at the time in a neurotic subject, and which are followed by some form of paralysis. And I think it highly probable that such a case as Dr. Putnam referred to would belong to that class — a slight injury, with a good deal of mental disturbance at the time, with a long continued functional process afterward, paralysis, loss of sexual power, etc.

I call to mind a case of a young lady who fell and hurt her knee. Partial weakening of the muscles of the injured extremity obliged her to use a crutch. The paresis lasted for many months, but was entirely cured by rest, with the usual treatment which accompanies the rest cure. The rest had relieved the exhaustion which had existed in the nervous centre, and the motions of the legs have been perfect ever since. It seems to me that we are not to apply the diagnosis of hysteria to these cases in a loose way, such as reading Dr. Page's book would incline us to do.

DR. E. H. BRADFORD: In view of the importance of this matter, and the difficulty of getting at the facts, I would like to make a motion that a committee of four and the secretary be appointed by this Society to make an investigation in the course of the coming year in regard to the late Bussey bridge disaster. The conditions for such an investigation are peculiarly favorable: We have an accident occurring very near Boston; the victims have been observed carefully by a number of very skilful physicians; we have a number of experts who have carefully examined the cases, and we have a railroad corporation which is particularly fair. In the course of the next year nearly all of these cases will have been settled, and I am quite sure, from what I have heard, that the railroad will give any assistance they can. We shall then learn what has been the result after litigation, how many have recovered and how many have not recovered. I think it will be of substantial value. [The motion was carried.]

DR. MORTON PRINCE: It has seemed to me that under this term, spinal concussion, there have always been included a very large number of different affections, and in particular among them have been included cases which are really cases of gross lesions of the cord. And the worst of it is that it was upon these last that the original doctrine of spinal concussion was founded, in consequence of which a taint has been given to the whole subject. These cases have been and are constantly overlooked because a thorough neurological investigation is not made. But aside from these cases of gross lesions I think that all cases of spinal concussion may be classed under at least four different heads.

First, we have cases which I think can be called traumatic hysteria, including under this term most cases of functional paralysis. I don't know that we can draw any sharp line of distinction defining the purely hysterical cases, and I prefer, for the sake of simplicity, to class them together. It does not seem to me, in the present state of our knowledge, that we can rigidly apply the name hysteria to anything more than a class of functional diseases. If we limit the term to the "grande hysterie" of Charcot, I don't know what we are to do with the large classes of paralyses which constantly occur, and in which we have no reason to suspect any organic lesion. These cases frequently occur, and, I think, comprise a certain portion of the cases of so-called spinal concussion. I have seen many of them, and have here the history of one which is striking in many points. It is the case of a soldier who was struck in the left side in 1862 by a piece of shell, or some other large missile. Being protected by his blanket, which was wound up and slung around him, the blow left no traces. He was taken to the hospital. The left side was paralyzed immediately after the accident, and has remained so ever since. On physical examination, made last May, I found: Paresis of left arm and leg; no atrophy or rigidity of muscles; nearly complete anæsthesia and analgesia of the leg as high as the middle of the thigh, and of the left arm as high as the middle of the upper arm; no sign of any injury to the side where he was struck; left knee-jerk more pronounced than the right; right feeble. This seems to me a case of purely functional disease: and in the light of our present knowledge best classed as hysteria. A similar, though a much simpler case, I saw the other day. It was that of a man who had fallen from a table or something of that sort and struck on his back against a brick. At the time I saw him, a month later, there was partial paralysis of the right arm, and he complained of pain between the shoulder-blades where he was struck, and round about the shoulders. I put a blister over the fourth dorsal vertebra, and he returned in high spirits, feeling perfectly well, and was able to go to work. This seems to me to be an example of a certain number of cases.

It seems to me that rather too much stress has been laid upon the fact as to whether the patient gets well or not after litigation to determine whether it is functional or not. I don't know why hysterical diseases after trauma should not exist as long as those occurring under other conditions. The first case has already lasted twenty-five years, and I have seen several such cases of greater or less severity.

And in this connection I may say that I am inclined to agree with Dr. Knapp in regarding a considerable proportion of the non-railway cases as incurable, or at least presenting an unfavorable prognosis. It is not very uncommon to meet such cases lasting for very long periods. I say non-railway cases, because in the cases following railway accidents there is an element of mental shock that does not enter at all, or only to a slight extent in the other cases. Hence it is that in "railway spine" or "brain" we have a mental factor playing such an important part. Conclusions drawn from the one class cannot incautiously be applied to the other. But because paralysis and other symptoms following concussion do not get well, it does not seem to me that we are justified in assuming an organic gross lesion, such as capillary hæmorrhages. They may still be functional, using that term as ordinarily applied to other affections. How many of the incurable cases are due to comparatively gross lesions can be settled only by future research. Further, it is possible that, as in other prolonged functional diseases, secondary changes may occur rendering recovery difficult.

Another large class should be regarded as traumatic neurasthenia. Many of them present symptoms simi-

lar to those we see every day in patients suffering from the wear and tear of life. I have, to-day, under my care a case of neurasthenia which, if there had been a traumatic history, would be typical of one of these cases of spinal concussion. If left to herself I think she would not get well for a long time, perhaps some years. In that case one might as fairly argue that there was organic disease at the bottom of it, as to claim it for traumatic neurasthenia. Under this class (of traumatic neurasthenia) I think the largest proportion of cases of spinal concussion may be placed.

A third group of cases may be classed as paralysis from idea. I may cite, as enabling us partially to understand this group, the case of a boy who ran across a railroad track with some other boys. He tripped and fell in front of an engine moving towards him. He tried to get up, but found it absolutely impossible to do so. His companions called to him to jump and run, but he could not do it, and told them to go on and leave him to his fate. Just before the engine reached him it was fortunately switched off, and at once he got up and ran away. There was complete paralysis from idea, though, I must admit, it may be fairly questioned whether it is not better explained by a reflex paralysis originating in the emotion of fear. Some of the so-called hysterical knees are better explained as paralyses from idea, as well as many common forms of local paralyses following local injuries.

In this connection I may parenthetically remark that drowning from so-called cramp may be better explained as due to a sudden paralysis of this nature.

But eliminating these three groups, does there still remain a fourth group of cases in which the symptoms can only be explained by a molecular derangement brought about by the physical concussion. While I do not think we can deny the existence of such cases, they must be few and far between. We may even give the Scotch verdict of "not proven." I have here a patient whom I desire to show to-night, who seems to me to have originally answered the requirements of the molecular theory as well as most of the recorded cases. This young man, while swinging on the parallel bars in a gymnasium, fell to the floor, striking on his neck. His feet at the time were high above his head. He did not lose consciousness; but he states, that, when asked by the instructor shortly after he fell, if he could move his legs, he tried and found he could not move either legs or arms. He had the feeling of "needles and pins" all over him. In the course of a few hours, he regained the use of his legs, but his arms remained paralyzed. The first night it was necessary to catheterize him, and he was constipated for some days. At the end of a few days, when I saw him, there remained only paresis of both arms; legs were normal; sensation unaffected; tenderness over fifth cervical vertebra, and he carried his head forward in a stiff constrained manner. The paresis of the arms persisted for about two and a half months and then disappeared. During this time there was no wasting of the muscles, and the electrical reactions were normal. At first I thought this a case of bona-fide spinal concussion; but I now think I was wrong, and that the lesion was probably a hæmorrhage upon the anterior surface of the cord pressing upon the anterior motor nerve roots before they joined the posterior sensory roots. The first general paralysis was probably due to shock. You see he has now completely recovered, and has perfect use of his arms, though he still carries his head forward from habit.

It seems to me, that in many cases, the psychical element plays a very important part. It seems to me that we must assume that it is the psychical shock, and not the physical shock that does the mischief. Patients have experienced almost every one of the customary symptoms, when they supposed they had been injured, although it was found afterward that no injury at all had occurred to them. Therefore it seems to me that it is the psychical influence that plays the dominant part, and not the physical. I think we must be very cautious how we accept the statements of patients in regard to their previous history, because any one who is at all conversant with the legal investigation of cases knows how almost impossible it is to get a correct history of cases previous to the accident; the patients themselves being unable to give a straight account of their previous condition, and when thoroughly known it is often found that there have been points in the history which were not known before, and which play an important part. This young man to-day is unable to state with anything like accuracy the history of his case, but luckily I have a record which was made at the time. In one of the cases reported by Dr. Knapp, my history, as told to me, differs from his in one respect. My notes show that the paralysis did not come on for two months after the wound, and as we know very little about what took place during those two months, it seems me a doubtful case from which to draw conclusions.

Dr. Knapp: During that time he was sick with peritonitis.

Dr. Prince: He says that he was in the hospital.

Dr. Knapp: No; the medical and surgical history of the rebellion tells that.

Dr. Prince: There still remains the possibility of syphilis.

Dr. Bullard: I will only say a few words. First, in regard to simulation of serious symptoms by patients; it has been my fortune to meet with comparatively few cases where I believe this to have occurred. The more I have seen of the class of cases under discussion, the more I am inclined to doubt that much simulation exists. There is no question that there are many patients who complain of symptoms which are entirely subjective; but certainly, in a large proportion of cases, these symptoms occur, and persist in a way altogether inexplicable on the simple ground that they are simulated.

There is another point of great importance in considering cases of this character, and that is the previous history. In persons predisposed to hysteria or of specially excitable nervous temperament, hysteria and other functional nervous disorders are more easily induced than in others of more healthy constitutions. This is a very important point to be considered in any case. An accident which will cause no serious injury to a person of healthy and vigorous health with no abnormal predispositions may produce very serious and lasting effects upon one with a tendency, whether active or latent, to functional nervous disorders (hysteria, neurasthenia, etc.).

It is therefore extremely important that we should ascertain as far as possible the previous history of the patient. This is often very difficult but it should be

sought for thoroughly, not simply on the ground mentioned, but also and even more because many of the symptoms which most frequently occur in these cases are liable to be produced by other causes, as syphilis, alcohol, lead, etc., and may or may not have existed previous to the injury. In all cases these possible causes should be as nearly as possible eliminated.

There is no doubt that under the term "railway spine" there are included a *variety* of pathological conditions. Some are no doubt functional in the sense that if we should examine the nervous system, we should with our present methods of examination, find nothing wrong; others are unquestionably organic.

There seems to me to be no safe course open in the present state of our knowledge on this subject, but that each case should be studied carefully *by itself*, and decided on its own merits.

DR. KNAPP: I would like to make one or two more remarks. I did not mention the statement made by Page that all of these disturbances occur in patients who have a pecuniary interest in the case, and he questions if such cases are ever seen in hospitals or out-patient clinics, when there is no pecuniary interest involved. I think that is characteristic of the statements that Mr. Page makes in his work; and it seemed to me, as I have said, that most of the cases that I have reported had no pecuniary interest whatever, which answers Mr. Page's criticism.

I think Dr. Prince is disposed to be a little too vague in what he calls hysteria. It must mean something or nothing. Hysterical, however, does not mean functional, the less cannot be properly used to mean the greater. If it is to be used as a general term, that is one thing; limiting hysteria to the sense in which I have employed it, I think we see very few cases of traumatic hysteria. Paralysis depending upon idea, is of course hysterical paralysis. As I intended to bring out in my paper, some of the cases that I have seen are neurasthenia, pure and simple.

Many of their symptoms were symptoms of undoubted organic disease; incontinence of urine, nystagmus, exaggeration of reflexes. These symptoms are not those of functional nervous disease. While I believe a part are neurasthenic, and another part functional, I do not wish to say that all cases that are functional are hysterical or neurasthenic. There are a good many functional diseases beside these, and it is a good idea to keep the boundaries as nearly fixed as we can. I think there are a good many cases where we find signs of some organic nervous disease, and the explanation of Westphal seems to me the most plausible for such cases.

Recent Literature.

A Practical Treatise on Diseases of the Skin. By JOHN V. SHOEMAKER, A.M., M.D. New York: D. Appleton & Co. 1888.

"All at once a conviction flashes through us that we have been in the same precise circumstances as at the present instance once or many times before." This quotation from "The Autocrat of the Breakfast Table" indicates with sufficient accuracy the dominant mental sensations derived from reading this treatise upon diseases of the skin by any one who is familiar with Duhring's work upon the same subject. The arrangement of the chapters and their various subdivisons is almost a replica of Duhring. Much of the text also bears a striking resemblance to that of the same author. There is some shifting about of sentences and ideas as well as alteration of individual words, but the framework is the same and to be recognized in spite of the altered verbal drapery with which it is hung. The following parallel columns will serve as *pièces justificatives* of this assertion. That the resemblance is not merely due to identity of subject, may be demonstrated by taking any treatise upon diseases of the skin other than that of Duhring — Hyde's or Robinson's for example — and making a like comparison.

DUHRING. (3d Edition.)	SHOEMAKER.
"Directly the reverse of hyperæmia is the condition termed anæmia in which there is a deficiency in the amount of blood in the cutaneous capillaries. This state may result from an absolute want of blood in the general system, in consequence of hæmorrhage, or it may follow disease, as in chlorosis. It is characterized by loss of the natural color of the skin, succeeded by a blanched whitish or yellowish hue, affecting according to its course and nature, either the whole surface or certain regions, as the extremities. It is also attended by a decrease in the temperature of the surface, and at times by cold sweating." [Page 80.]	"Anæmia of the skin is symptomatic of a deficient amount of blood in the cutaneous capillaries. It may be the result of disease or may be due to excessive loss of blood from the general system by hæmorrhage. It is characterized by unatural pallor which may be succeeded by a yellowish or greenish hue involving all or a great portion of the skin. It is usually attended by a decrease in the surface temperature, and may be accompanied by profuse perspiration." [Page 47.]
"Seborrhœa is a disease of the sebaceous glands, characterized by an excessive and abnormal secretion of sebaceous matter, forming upon the skin an oily coating, crusts, or scales." [Page 115.]	"Seborrhœa is a functional disease of the sebaceous glands, characterized by an excessive and altered condition of the sebaceous secretion, forming an oily coating, crusts or scales upon the skin." [Page 92.]
"Ordinarily they consist of torn points, lines or streaks more or less furrowed with shreds of epidermis variously sized and shaped for the most part irregular, showing reddish moist surfaces, oozing minute quantities of serum and blood which have a tendency to dry into crusts." [Page 62.]	"They vary in size and shape, but generally consist of torn points or linear furrows, from which minute particles of blood or serum are oozing, or which have dried up and formed a crust over the lesions." [Page 40.]
"Epithelioma may be confounded with syphilitic tubercles and ulcerations, accuminated warts, lupus and the rare affection, rhinoscleroma. The papule or ulcer of epithelial cancer especially if about the genitalia, may also resemble the chancre, but attention to the history to the duration of the lesion, and to other points of diagnostic value will aid in arriving at a correct opinion. The evolution of late syphilitic formations is always much more rapid than that of cancerous, only rarely in malignant cases does epithelioma run a rapid course. The characters, moreover, of the ulcerative process due to syphilis is very different from that of epithelial cancer. In tubercular syphilis, two, three or more points of ulceration are apt to exist, in cancer, usually only one. In syphilis the secretion is generally abundant, yellowish and creamy, in cancer it is scanty, streaked with blood, viscid and stringy. The condition of the tissues surrounding the ulcers, is also different. In the infiltrating variety of cancer there is more or less induration, in syphilis there is none, the deposit generally terminating abruptly against the sound skin. In cancer there is apt to be pain of a lancinating character, in syphilis the ulcer is usually without pain." [Page 555.]	"The diagnosis of epithelioma is easy in advanced stages of the disease, but the disease might in the beginning of an attack be confounded with the lesions of syphilis and lupus vulgaris or with ordinary warts, simple condylomata or seborrhœa sicca. The papule or nodule of epithelioma may at first resemble a hard chancre, but the history of the case and the course and duration of the lesion will soon point to the correct diagnosis. The epitheliomatous ulcer might at first sight be confounded with a tertiary syphilitic ulcer, but syphilitic ulcers are usually multiple, while epithelioma is almost invariably single. The secretion in syphilis is fetid, yellow and abundant, while in epithelioma it is usually blood-streaked, viscid and scanty. Epithelioma is usually surrounded by a well-marked zone of infiltration, which is either absent or insignificant in syphilis. Finally, epithelioma is a disease of long duration accompanied by severe lancinating pain while the ulceration of syphilis runs a comparatively swift course and is not attended with any pain." [Page 463.]

This resemblance is diffused throughout the book. In those portions which relate to therapeutics, where

the author exhibits more independence, the defect which is most conspicuous in Duhring's work is apparent also in this; namely, a want of perspective in handling the subject, a discursiveness of recommendation and vagueness of direction which render it difficult for the student always to make up his mind exactly what is the best thing to do. A long list of formulæ ends the book which is not without decided merit, but which to all intents and purposes may be regarded as a later and improved edition of Duhring. G. H. T.

The Throat and its Diseases, including Associated Affections of the Nose and Ear. With one hundred and twenty illustrations in colors and two hundred engravings, designed and executed by the author, LENNOX BROWNE, F.R.C.S.E., Senior Surgeon to the Central London Throat and Ear Hospital, etc. Second edition. Rewritten and enlarged. Philadelphia: Lea Brothers & Co. 1887.

This is a very practical and original work. It is intended especially for general practitioners, and can be cordially recommended to them. To the specialist it will be of interest, as it is a mirror of the author's own practice and ideas concerning a class of diseases which for many years he has had rare clinical opportunities for observing.

As Mr. Browne tells us that his work has no pretensions to be considered exhaustive, we need not find fault with him for the incomplete manner with which he has disposed of some of the important affections of the nose and naso-pharynx. He has evidently written his book *con amore*, and those subjects of special interest to himself are thoroughly treated. The chapters, for instance, on inflammation of the submucous tissue of the larynx — œdema — syphilitic laryngitis, and especially those on tuberculous laryngitis, and lupus of the mouth, pharynx, and larynx, are worthy of all praise.

In Chapter I, in speaking of the action of the crico-thyroid muscle, the author erroneously states that its office is to draw the thyroid cartilage downwards. Its action, however, which is to pull the cricoid upwards, is also given; but then the author adds that, "practically, the point is not one of great importance, since the effect of the muscular movement is, in either case, equally to stretch the vocal cords." It is quite true that the cords would, in either case, be stretched. It seems to us, however, that those who like to know the right from the wrong must consider it important to have a correct idea of how this muscle acts, since perfect vocalization is impossible without tension of the vocal cords, and this tension is controlled by the crico-thyroid muscles and the expiratory blast of air carrying the cricoid cartilage upwards on to the thyroid. The thyroid cartilage, owing to the powerful muscles attached to it, is the fixed point.

In the chapter on "Therapeutics of Throat Diseases," the use of sprays to the larynx and the administration of snuffs in nasal diseases is condemned as being unphysiological, seldom beneficial, and often deleterious. The only conditions in which the author has found powders of benefit are tuberculous thickening and ulceration of the epiglottis, and in malignant diseases. Considerable stress is laid upon the value of "Leiter's Temperature Regulators" in cases of tonsillitis and other acute inflammatory troubles of the fauces and larynx.

The subjects of acute laryngitis, exudative inflammation of the larynx, and diphtheria are ably discussed. Acute laryngitis in children and in adults is considered to be one and the same affection; the features of distinction being due to the age at which the attack occurs, and not to any difference in its morbid anatomy. Mr. Browne insists that the severity of inflammations of the larynx in the young is due to the greater tendency in children to plastic exudation, as a result of simple mucous inflammations. The small size of the larynx in the child may also influence the severity of infantile laryngitis. By exudative laryngitis or croup the author means a pseudo-membranous inflammation of the air-passages of an essentially non-infectious and non-contagious nature, which exhibits local, rather than constitutional symptoms. This disease is considered to be altogether distinct and different from diphtheria.

In the chapter on malignant neoplasms, some points on the lymphatic system in relation to isolation of cancer in the larynx are brought out which are interesting, and which are not generally recognized. It is shown that the lymphatics of the larynx are not isolated, and that it is by no means true that that portion of the larynx which is usually attacked by carcinoma is ill supplied with lymphatics. Two beautiful illustrations from Sappey's "Atlas of the Lymphatic System" are given, as well as full quotations from his writings on this subject. In speaking of abnormal sensations in the pharynx, such as heat, pricking, swelling, weight, some foreign body, or the *globus hystericus*, Mr. Browne expresses the opinion that such feelings are always symptomatic of some objective cause; the principal condition which gives rise to them being a varicose condition of the veins at the base of the tongue. A sensation to taste, and sometimes the actual presence of blood in the mouth on rising from sleep, is believed to be characteristic of varix of the tongue, of the mouth, or of the pharynx. Neuroses of the larynx are disposed of in a very few pages. "Abductor" paralysis receives but brief notice, as Mr. Browne does not consider it a subject of any practical importance. We may here, in passing, call attention to Figures 96 and 97 (Plate x), where the author pictures what he calls paralysis of the left abductor. We see no evidence whatever that the left abductor is alone paralyzed. To us, the appearances in inspiration and in phonation are typical of complete paralysis of the recurrent nerve, and, consequently, of the whole group of muscles attached to the left cord. When a vocal cord is observed to be completely immovable, we have never been able to understand what justifies the assertion that only one particular muscle is paralyzed, and not two or more muscles of the laryngeal group. The *position* which the paralyzed cord assumes is no criterion, since we see it in different positions, according to individual peculiarities, when the recurrent nerve is wholly destroyed. Most of the illustrations in this work are from Mr. Browne's own brush or pencil. They are very numerous, beautifully drawn, and are an important feature of this excellent book, which will meet the needs of the general practitioner, and which no laryngologist ought to be without.

SANITATION SOCIOLOGICALLY CONSIDERED.[1]

THE city of Glasgow is fortunate in having as its health officer, a physician of keen perception, and one who is alive to the sanitary welfare, not only of the people of his charge, but of mankind in general.

A recent address by Dr. Russell is especially worthy of the perusal of all sanitarians. In this address, entitled "Some Sociological Aspects of Sanitation," he discusses some of the arguments offered by Herbert Spencer, wherein the latter states the law of "right social relationships, that every man has freedom to do all that he wills, provided that he infringes not the equal freedom of any other man." Dr. Russell does not question this principle, but rather its application to sanitation. "It is only when we follow Mr. Spencer into the details of his method of dealing with public health that we can discover whither he would lead us. He maintains that it is not the duty of the State to protect the health of its subjects, and that sanitary administration by State and municipal authorities is wrong. All taxation for sanitary administration being the abstraction from the citizens of more property than is needful for the sufficient defence of his rights, is to be condemned. . . . It follows that neither the past, present nor proposed methods of securing the health of towns, are equitable." Mr. Spencer goes on to sketch a model method of sanitation of his own proposal. "Respecting sewerage there would be no difficulty. Houses might readily be drained on the same mercantile principle, that they are now supplied with water. It is highly probable that, in the hands of a private company, the resulting manure would not only pay the cost of collection, but would yield a considerable profit. . . . Paving and lighting would properly fall to the management of house-owners. Were there no public provision for such conveniences, house-owners would quickly find it their convenience to furnish them.

"If this is said to be impracticable, Mr. Spencer replies that therein lies the virtue of the scheme; for the impracticability arises from the imperfect morality of mankind, and perseverance in these impracticable methods will elevate the general morality until it becomes practicable. If, out of the intermediate chaos will arise disease, which will involve good and bad, he welcomes disease, especially epidemic disease as one of the saviors of society. Partly by weeding out those of lowest development, and partly by subjecting those who remain to the never-ceasing discipline of experience, nature secures the growth of a race who shall both understand the conditions of existence, and be able to act up to them." And thus we are introduced by Spencer to the doctrines of "natural selection" as applied to sanitary laws. He regards the methods of sanitation now in vogue as calculated to further the "survival of the unfittest."

Dr. Russell in commenting upon these paragraphs from Spencer[2] considers the comparative value of disease as a factor in natural selection in civilized man and in the lower animals. "We must not think of disease," he says, "or rather its causes, merely as producing death, as we are apt to do, when the elevation of the race, by the extinction of the individual fills up our field of vision. Disease is not like the deer-stalker's bullet when his aim has been true, and one falls while all the rest of the herd gallop away unharmed. It resembles the discharge of 'buck-shot' or 'sparrow-hail' which scatters, and for every one killed there are a number maimed. Granting, then, that the most unfit dies, round every *deceased* unfit there are a number of *surviving* more or less unfit, because of the effects of disease. This is the invariable result of the action of disease or disease-producing agencies on life. But in the lower animals the predatory instincts of one order promote the development of another by killing and devouring its weaklings, and within the order itself sexual selection tends to isolate the individual from posterity. In civilized man the weaklings survive, and sexual selection does not effectively prevail. The analogy is perfect between the effects, immediate and remote, of a cartridge fired at a large covey and a volley on the battle-field, and the comparative value of disease as a factor in natural selection in these cases. In the former there are the dead which are bagged by the sportsman, and the wounded who are eaten before nightfall by hawks, weasels, cats, etc.; in the latter there are the dead who are buried, and the wounded who are carried away and survive with various deformities and injuries. If you want full evolutional value out of disease in man, regarded merely as an animal, you must kill or seclude from society; but killing is murder, and sexual selection can only be promoted by the diffusion of knowledge and the elevation of morality to such a sublime pitch that the individual will limit his happiness, subdue his desires, and in short, extinguish himself for the benefit of posterity."

Dr. Russell concludes, that, under existing circum-

[1] "On Some Sociological Aspects of Sanitation," by James B. Russell, B.A., M.D., LL.D., President of the Philosophical Society, of Glasgow. The President's Address, November 2, 1887.

[2] Social Statics. 1868.

stances the most efficacious and direct method of promoting the survival of the fittest in civilized man is to prevent disease of all kinds by the removal of its causes. But different diseases present different sociological aspects, some begin and end in the individual, and do not descend vertically, or spread laterally as morbid entities. Their value in the process of selection is confined to the extinction or the weakening of the staying-power of the individual. Simple inflammations like pleurisy and pneumonia, are examples of this class.

Other diseases, as gout, insanity, etc., descend or tend to descend, vertically. They are distinctly hereditary. Others, again, are remarkable for lateral extension from person to person, from town to town, from country to country. These do not descend vertically, and influence posterity only indirectly in the same ways as the first class. But they stand out as the most potent sociological disease factors in virtue of their power of lateral extension or infectivity.

Dr. Farr says of the diseases of this class: "They distinguish one country from another, one year from another; they have formed epochs in chronology; and, as Niebuhr has shown, have influenced the fate, not only of cities such as Athens and Florence, but of empires; they decimate armies, disable fleets; they take the lives of criminals that justice has not condemned; they redouble the dangers of crowded hospitals; they infest the habitations of the poor, and strike the artisan in his strength down from comfort into helpless poverty; they carry away the infant from its mother's breast, and the old men at the end of life; but their direst eruptions are excessively fatal to men in the prime and vigor of age." This last statement is not exactly in harmony with Spencer's "sweeping away by pestilence tens of thousands of unhealthy livers;" or the "weeding out those of lowest development."

Dr. Russell then proceeds to sketch with a masterly hand the most important communicable diseases, and finally sums up their common characteristics as follows:

(1) *The property of lateral extension.*

(2) *The habit of endemicity,* or of lurking in the intervals between epidemics in places where the conditions are peculiarly favorable to the maintenance of the disease.

(3) *The artificial and therefore remediable nature of the local conditions which foster endemicity.* These conditions are essentially of the nature of uncleanliness.

(4) *Even those communicable diseases, such as small-pox, measles, scarlet-fever and whooping-cough, which can scarcely be said to live upon uncleanliness, but attack man as man, are all aggravated thereby.*

(5) *The soil which sustains the communicable disease in the epidemic condition, and promotes the epidemic expansion is the same which produces general unwholesomeness.* In short, the adoption of radical measures for preventing epidemics covers the whole field of sanitation.

(6) *Whoever persists in a manner of life calculated to produce or promote communicable disease injures himself first, but next, and with certainty, his neighbor.* Carlyle, in quoting Alison's story of the poor Irish widow, answers the question, "Who is my neighbor?" as used in this connection. Her husband died of typhus "in one of the lanes of Edinburgh," and she wandered about the town with her three children, seeking help, and finding none returned to her lane, and died there, and set a-going a local epidemic which ended in the death of "seventeen other persons." "Very curious," says Carlyle. "The forlorn Irish widow applies to her fellow-creatures, as if saying, 'Behold, I am sinking, bare of help; ye must help me! I am your sister, bone of your bone, one God made us; ye must help me.' They answer, 'No, impossible; thou art no sister of ours.' But she proves her sisterhood; her typhus fever *kills* them. They actually were her brothers, though denying it! Had human nature ever to go lower for a proof?"

"It certainly was low enough," says Dr. Russell, "but human nature requires such arguments, and the ultimate cause of the existence of communicability in disease is, I believe, to enforce the golden rule upon us in reference to the physical well-being of mankind. For 'who is my neighbor' in this aspect? Not only is the Irishman in his miserable hut neighbor to Dives in Belgravia, but the Polish Jew in his filthy 'quarter'; not only the unvaccinated children of Leicester, but the unvaccinated French-Canadian; the Mahommedan pilgrim, who drinks at Mecca the waters of the sacred well of Zem-Zem, which the profane chemist tells us is polluted with sewage and a main factor in the dissemination of the cholera which he carries a long stage on its journey to Europe. Indeed, in these days rapid transit has so shrivelled up space, and commerce so intermingles and distributes articles of trade which may carry disease, that it is hard to say who in the wide world may not prove their affinity to me as forcibly as my next-door neighbor.

"The practical question is, 'What am I to do with my dirty neighbor?' and we must bring to the solution of it a little common-sense and ordinary business principles as well as philosophy. The first thing to be done is to make him a voting unit in some convenient area of local government. Impose upon local administrative bodies the duty of providing the physical conditions and appliances of health, such as water-supply, sewerage, drainage, infectious hospitals, disinfecting apparatus, and of carrying out the daily operations, such as scavenging and sanitary supervention, necessary to keep the district clean outside and inside the houses of the inhabitants. To provide against the contingency of my dirty neighbor having a local majority, as well as to maintain a staff of higher capacity to advise in special emergencies and hold local inquiries, let there be at the head of the sanitary administration of the country a local government board, armed with power to enforce the performance of such duties as, being neglected, first injure the locality, but

next involve a risk to the general well-being of the country. The local administrative must, of course, have parallel power of prosecuting and punishing the dirty neighbor for overcrowding and other nuisances which affect the well-being of the neighborhood.

"The solidarity of human interest in the face of communicable disease has in recent times asserted itself far beyond the submerging of the individual. Nations are now learning that organization, to be equal to the task of successfully resisting the inroads of such diseases as cholera, yellow fever, and small-pox, must embrace not only local authorities within nations, but nations themselves. Even the United States, with all its jealousy of central interference with the doings of individual States, learned from the ravages of yellow fever in the Mississippi Valley in 1878 that some general coördination and direction was necessary for the national good, and hence the act establishing a National Board of Health passed by Congress in the following year. In Europe the same powerful agency has brought governments into negotiation. Step by step the final end of the existence of communicable disease is being worked out. Self-interest enlists the most enlightened nations in the promotion of the physical welfare of the poorest and most wretched inhabitants of the remotest corners of the earth."

AN ILLUSTRATION OF MEDICAL BULLETINS.

THE catalogue of ills in the last bulletin of General Sheridan's physicians, as published in Boston daily papers, is a good illustration of the difficulties and annoyances to which the physicians of public men are subjected. The bulletin read as follows, in a paper of wide circulation, which has done much to popularize medical knowledge:

"The immediate cause of death was heart failure. The remote cause was disease of the mitral and aortic valves, the existence of which was known to his physicians, to himself and to his family in November of last year. The complications which have occurred have been nervous exhaustion, pulmonary insarctions, pneumonia, pulmonary fegeria, anasarca and hemorrhages."

The complications varied somewhat in other papers, thus:

"Nervous exhaustion, pulmonary insarctions, pneumonia, pulmonary œgeria, anasaca and hemorrhages."

"Nervous exhaustion, pulmonary insarctions, pneumonia, pulmonary, œgeria, anasaca and hemorrhages."

"Nervous exhaustion, pulmonary anasarctions, pneumonia, pulmonary œgeria, anasarca and hemorrhages."

The physician must be brave even to rashness who confides a delicate diagnosis to the telegraph and the daily press.

ARMY MEDICAL EXAMINATION.

THE JOURNAL publishes to-day a notice of the organization of an Army Medical Board, which will meet in New York City on the 1st of October, for the examination of candidates for the Medical Corps of the Army, a notice for which we doubt not many young medical men look with interest. The army service is in one respect, certainly, an attractive one. It has room for men with special tastes for literary and scientific work, and knows how to utilize such men for their own and the general welfare.

MEDICAL NOTES.

— Another man jumped from the Brooklyn bridge August 3d. His name is Matthew Byrnes, and his age twenty-one. He was picked up by the tug Cheney, which was towing the floating hospital of St. John's Guild down the bay. When off Governor's Island he was transferred to another tug, which carried him to the Hamilton ferry slip. He was subsequently taken to the Long Island College Hospital, where he was examined. His back, the calves of his legs and the back of his arms were marked with black-and-blue ridges. He said he felt no pain internally, but complained bitterly of the cold. Whiskey and hypodermic injections were freely administered to him, and he was enveloped in several blankets. When asked how he felt, he replied, "All right every way, but I'm cold." A few minutes later, after a second hypodermic injection had been administered, he shouted "Stop that; this is the tenth time you have stuck me with that needle." Soon after he fell asleep. He will probably recover, and if so, will be arraigned in the court. He is unmarried.

BOSTON AND NEW ENGLAND.

— Boston papers have recently contained the story of the refusal of the police to permit the use of a police ambulance to transfer a sick man to the hospital. It may be interesting to physicians of the city to know that the use of the police ambulances is restricted to accidents.

— The amount of patent medicines received at General Sheridan's cottage at Nonquitt, from well-meaning admirers, would, it is said, fill a small apothecary shop. The doctors, also, were deluged with advice by mail, about the treatment the patient needed. It came from all over the country, like the patent medicines.

— Judge Aldrich, of the Superior Court, granted an injunction, August 2d, restraining Dr. Frank L. Weir from practising as a physician in Taunton, Mass., or within ten miles of Taunton Green for five years, under an agreement made with the plaintiff in this case in July, 1887. The plaintiff, who went abroad, leaving his patients in the care of the defendant, alleged that in violation of the contract, the defendant had opened an office in Taunton.

— We learn from the daily papers that the thirty-five cases against the Boston & Providence Railroad Company, which arose from the "Bussey Bridge" accident, and were placed in the charge of one Boston lawyer, have been settled without a trial, two of the

cases being referred to arbitrators. In the case of Oscar H. Norman, the arbitrators awarded the plaintiff $18,000. The highest amount received for any one injured in the accident was $25,000, and it is understood that the whole cost to the company was $100,000. The bills of physicians paid by the company are said to have been about $100,000. It is stated that the fees of Mr. Winslow Warren, who acted for the company in settling claims, exceeded $50,000.

NEW YORK.

— An ordinance has been adopted by the Board of Health requiring that at every hospital and dispensary in the city one or more rooms shall be provided for the reception and isolation of persons suffering from contagious disease.

— The attention of the Board having been called to the practice of undertakers carelessly throwing ice which has been used about dead bodies into the streets, where it is apt to be picked up by children and carried to their homes, the Secretary of the Board has been directed to notify all undertakers that the practice must be discontinued.

Miscellany.

A NEW QUARANTINE ACT.

The following is the quarantine act which passed the Senate May 3, 1888, passed the House July 23, 1888, and was approved by the President August 2, 1888. Its provisions go into immediate effect, and the quarantine buildings will be erected as soon as practicable. Steps will be immediately taken to secure sites for the quarantines not now on Government land:

AN ACT TO PERFECT THE QUARANTINE SERVICE OF THE UNITED STATES.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That whenever any person shall trespass upon the grounds belonging to any quarantine reservation, or whenever any person, master, pilot, or owner of a vessel entering any port of the United States, shall so enter in violation of section one of the act entitled "An act to prevent the introduction of contagious or infectious diseases into the United States," approved April twenty-ninth, eighteen hundred and seventy-eight, or in violation of the quarantine regulations framed under said act, such person, trespassing, or such master, pilot, or other person in command of a vessel shall, upon conviction thereof, pay a fine of not more than three hundred dollars, or be sentenced to imprisonment for a period of not more than thirty days, or shall be punished by both fine and imprisonment at the discretion of the court. And it shall be the duty of the United States attorney in the district where the misdemeanor shall have been committed to take immediate cognizance of the offense, upon report made to him by any medical officer of the Marine-Hospital Service, or by any officer of the customs service, or by any State officer acting under authority of section five of said act.

Sec. 2. That as soon after the passage of this act as practicable, the Secretary of the Treasury shall cause to be established, in addition to the quarantine established by the act approved March fifth, eighteen hundred and eighty-eight, quarantine stations, as follows: One at the mouth of the Delaware Bay; one near Cape Charles, at the entrance of the Chesapeake Bay; one on the Georgia coast; one at or near Key West; one in San Diego Harbor; one in San Francisco Harbor; and one at or near Port Townsend, at the entrance to Puget Sound; and the said quarantine stations when so established shall be conducted by the Marine-Hospital Service under regulations framed in accordance with the act of April twenty-ninth, eighteen hundred and seventy-eight.

Sec. 3. That there are appropriated for the purposes of this act the following sums, out of any money in the Treasury not otherwise appropriated, for the construction, equipment, and necessary expenses of maintaining the same for the fiscal year ending June thirtieth, eighteen hundred and eighty-nine.

[Here follow the specific appropriations for 1889, which are substantially as follows:

For the Delaware Breakwater quarantine, $75,000; for the quarantine station near Cape Charles, Virginia, $112,000; for the South Atlantic Station (Sapelo Sound), $38,500; for the quarantine near Key West, $88,000; for the Gulf quarantine (formerly Ship Island), provided for by the act of March fifth, 1888, $15,000; for the quarantine station, San Diego Harbor, California, $55,500; for the quarantine station at San Francisco, California, $103,000; for the quarantine station at Fort Townsend, $55,500.]

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

CIRCULAR No. III.

WASHINGTON, D. C., July, 1888.

The Committee of Arrangements takes pleasure in announcing to the members and invited guests of the special societies taking part in the Congress that the arrangements are sufficiently advanced to assure the success of the First Triennial Session of the Congress of American Physicians and Surgeons, which will be held in the city of Washington during the 18th, 19th, and 20th of September next.

A number of distinguished physicians and surgeons have signified their acceptance of the invitation to attend, among whom may be named Sir Spencer Wells, Sir Andrew Clark, Sir William McCormac, Drs. W. O. Priestley, William Ord, and Grainger Stewart, Mr. Lawson Tait, Mr. Victor Horsley, Mr. Thomas Bryant, Mr. Thomas Annandale, Professors Ferrier, Esmarch, and Gerhardt, Drs. Rafael Lavista, of Mexico, J. L. Reverdin, of Geneva, O. W. Holmes and H. I. Bowditch, of Boston, Joseph Leidy, of Philadelphia, W. Kingston and Eccles, of Canada.

The preliminary programmes of the participating societies have been published. It is hoped the classified and final programmes will be forwarded without further delay. Several are already in possession of the Committee. As soon as all are received, the final programme of the Congress will be printed and distributed.

Places of meeting for the Congress and each of the

societies have been secured, conveniently located, so that members may interchange attendance without annoyance.

The meetings of the Congress will be held during the evenings, beginning at 8 o'clock P. M; on the evenings of the 18th and 19th the meetings will be held in the main hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue, and on the last (Thursday evening) in the hall of the National Museum. During this evening the Army Medical Museum and Library Building, alongside of the Museum Building, will be lighted and opened for the inspection of the members and invited guests. The meetings of the societies will be held during the day, according to the programme each may respectively provide. The sessions will be open to the profession.

On Monday evening, September 17th, a dinner will be given by members of the Congress to the guests of the participating societies. Invitations to this dinner will be sent only to the specially invited guests who have indicated their acceptance. The contributing members will receive cards of admission. It will be limited exclusively to members of the Congress and invited guests.

An informal collation will be served at Willard's Hotel on Tuesday evening, after the adjournment of the meeting of the Congress, to the guests and those members who may choose to attend. A similar entertainment will be served in the National Museum Building on Thursday night, after the final adjournment of the Congress.

Guests are requested to notify the Chairman immediately after their arrival in Washington, giving their address, and stating whether they have ladies with them. Special arrangements will be made for the entertainment of the wives and daughters of the guests.

Hotel accommodations are ample, and conveniently located to the places of meeting.

The Secretaries of the special societies are requested to forward to the Chairman the names and addresses of their foreign guests.

Members of the Congress and their guests are expected to register. A parlor in Willard's Hotel will be provided for that purpose, from which the mail of the members and guests will be distributed, and at which the city residence of each member or guest can be ascertained.

All communications should be addressed to the Chairman of the Committee.

SAMUEL C. BUSEY, M.D.,
1545 *I St. N. W., Washington City,*
Chairman Committee of Arrangements.

EXAMINATION FOR THE ARMY MEDICAL CORPS.

An Army Medical Board will be convened in New York City, New York, October 1, 1888, for the examinations of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the Army.

Application for an invitation should be addressed to the Secretary of War, stating date and place of birth; place and State of permanent residence, and accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character and moral habits; testimonials as to professional standing, from the Professors of the Medical College from which the applicant graduated, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a Regular Medical College, evidence of which, his diploma, must be submitted to the Board.

Further information regarding the examinations and their nature, may be obtained by addressing the Surgeon General, United States Army, Washington, D. C.

Correspondence.

ABSCESS OF THE BRAIN.

VALPARAISO, May 14, 1888.

MR. EDITOR, — In the report of the meeting of the Suffolk District of the Massachusetts Medical Society, held January 11th, the discussion following the reading of Dr. Bullard's paper on "A Case of Cerebral Localization" was interesting; but what most forcibly called my attention was Dr. Bradford's statement that the sense of the meeting seemed, in reference to cerebral surgery, to be one of disparagement.

During my service as house-surgeon in the Boston City Hospital under the late Dr. Thorndike, it was my good fortune to see him trephine in a case of old injury to the skull, where years later cerebral symptoms developed, showing such persistent and progressive character that operative interference seemed demanded. Trephining was done, and I have never forgotten the look of that bulging, pulseless brain. Dr. Thorndike, with a narrow-pointed bistoury, boldly made a plunge into the brain, but failed to locate the abscess. He was then requested to make another attempt in a forward direction, but replied, "I do not feel warranted in doing more." The stupor increased, and the patient died that night; and at 7 A. M., when we went to the morgue to continue the search for the cause of the compression, it was a disappointment to find that the friends had removed the body immediately after death.

The case, however, impressed me deeply; and owing to the confirmatory tenseness and pulselessness of the brain, I always felt there was an abscess, and determined that should another such case present I would not fail to urge or continue the search.

The experience thus gained proved useful in the case of an United States sailor, whom, through the courtesy of Dr. Clark, Surgeon U. S. frigate *Hartford*, I was asked to see in consultation, in company with Olof Page, M.D., (University of Pennsylvania).

While on shore the sailor had received a scalp-wound, he knew not how. This was seen by the assistant surgeon, who cleansed and closed it by sutures. Suppuration, however, set in, and the wound had to be reopened. Two months later he had an epileptiform seizure, followed by headache, increasing drowsiness, stupor, and a falling pulse, which, when seen, was 46. Ether was administered, and Dr. Clark operated, making a crucial incision over the seat of injury, thereby disclosing a fracture, and with a trephine one inch in diameter, removed a section of bone. The membranes appeared healthy and natural, but attention was called to the bulging, pulseless brain, as indicating deeper trouble. A hollow needle was pushed into the central portion without result, and a second plunge made was followed by a like result. The aspect of the case was such that, on consultation, it was urged that another opening be made following the course of the line of fracture. This was done, and disclosed the brain membranes, as before, apparently healthy, but still unduly tense and full. Here, again, the aspirating needle did not reveal anything; though sanguine still of ultimately finding the seat of trouble, at my solicitation Dr. Clark consented to once more make an attempt, using a pointed grooved director which I had carried. This he employed, and pus welled up along the director. Over an ounce of pus flowed out through the crucial incision which the doctor then made through the intervening brain substance. The cavity was washed out with $\frac{1}{100}$ carbolic solution, and a drainage-tube inserted. The effect on the pulse was instantaneous, as it rose at once to 78. Recovery followed without interruption, and within a few weeks the patient walked to my office to report, the cavity filled and wound closed.

The report of such cases as this of Drs. Bullard and Bradford are instructive as establishing the localization of lesions; and such cases strengthen the confidence and assurance of both the operators and their assistants for

future work. I feel sure that they would in future be more ready to operate; and certainly, but for the experience with the case in the Boston City Hospital, it is not probable that the search for the abscess in the case related would have been continued.

Only recently the boldness engendered bore fruit in an unexpected way. The writer was asked by Dr. O. Page to a consultation over a case under his charge in the German Hospital of this city. The patient was a lad, twelve years of age, who for three or four days had been off his food, moody, complaining of headache, photophobia, with constipation, vomiting and fever. The evening previous he fell out of bed in a convulsion, and when seen had been for twenty hours in an unconscious state, breathing stertorously, and with a slow pulse. Meningitis was the diagnosis made, tuberculosis excluded, from the history and previous knowledge of the boy. He was a wild chap, and the question arose, Could it be of traumatic origin? though previous to the convulsion he had denied any blow or fall on the head. However, on examining the shaved head, a marked irregularity was detected at one spot over the left parietal bone, as though there were a distinct depression. In view of his condition, we determined to cut down to the bone, and, if there were the slightest indication of injury, proceed to trephine. No attempt to check the bleeding was made; but having denuded the bone, we could find nothing to warrant further procedure. The following day the lad was perfectly conscious, continued to improve, and made a good recovery. No trephining was done, but the intention to proceed with it, even on a mere chance of benefit, led to the local bleeding, which did undoubted good, and changed the aspect of the case from one of fatal prognosis to recovery. Yours respectfully,

JOHN TRUMBULL, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 28, 1888.

Deaths reported 3,392: under five years of age 1,872; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,309, consumption 309, acute lung diseases 149, diarrhœal diseases 967, diphtheria and croup 92, typhoid fever 68, whooping-cough 49, measles 44, scarlet fever 40, malarial fever 29, cerebro-spinal meningitis 13, erysipelas two, puerperal fever two, small-pox three. From whooping-cough, New York 20, Washington eight, Chicago seven, Brooklyn five, Philadelphia, Boston and New Orleans two each, Baltimore, Pittsburgh and Cambridge one each. From measles New York 23, Chicago eight, Pittsburgh and Worcester three each, Brooklyn and Baltimore two each, Philadelphia, Fall River and Lawrence one each. From scarlet fever New York 19, Brooklyn and Chicago seven each, Philadelphia and Baltimore two each, Washington, Fall River and Brockton one each. From malarial fever, New Orleans nine, New York six, Brooklyn, Baltimore and Washington four each, Philadelphia one. From cerebro-spinal meningitis, Chicago five, New York three, Springfield two, Philadelphia, Baltimore and Worcester one each. From small-pox Philadelphia three, From erysipelas Brooklyn and Newton one each. From puerperal fever, Chicago and Washington one each.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending July 14th, the death-rate was 15.7. Deaths reported 2,835: infants under one year of age 755; acute diseases of the respiratory organs (London) 164, diarrhœa 130, whooping-cough 68, measles 45, diphtheria 36, scarlet fever 34, fevers 30, small-pox (Preston six, Sheffield two, London, Bolton and Leeds one each,) 11.

The death-rates ranged from 10.6 in Bristol to 28.5 in Bolton: Birmingham 14.8; Blackburn 11.4; Bradford 16.1; Hull 12.4; Leeds 17.5; Leicester 15.6; Liverpool 16.8: London 15.7; Manchester 23.7; Nottingham 13.3; Sheffield 13.1; Sunderland 19.0.

In Edinburgh 16.3; Glasgow 16.4; Dublin 22.6.

The meteorological record for the week ending July 28, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, July 28, 1888.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FOR THE WEEK ENDING AUGUST 4, 1888.

WOLVERTON, WILLIAM D., major and surgeon U. S. A. Is relieved from duty at Washington Barracks, D. C., and ordered to duty at Fort D. A. Russell, Wyo. By Paragraph 13, S. O. 173, A. G. O., July 27, 1888.

GARDNER, WILLIAM H., major and surgeon U. S. A. Is relieved from duty at Fort McHenry, Md., and ordered to duty at Washington Barracks, D. C. By Paragraph 13, S. O. 173, A. G. O., July 27, 1888.

CALDWELL, DANIEL G., major and surgeon U. S. A. Is relieved from duty at Fort D. A. Russell, Wyo., and ordered to duty at Jefferson Barracks, Mo. By Paragraph 13, S. O. 173, A. G. O., July 27, 1888.

KOERPER, EGON A., major and surgeon U. S. A. Relieved from duty at Fort Keogh, Mont., and ordered to duty at Fort Walla Walla, Wash. Ty. Paragraph 5, S. O. 175, A. G. O., July 30, 1888.

HARVEY, PHILIP F., captain and assistant surgeon U. S. A. Relieved from duty as assistant to the attending surgeon at Washington, D. C., and ordered to duty at Fort Keogh, Mont., Paragraph 5, S. O. 175, A. G. O., July 30, 1888.

BYRNE, CHARLES B., captain and assistant surgeon U. S. A. Is relieved from duty at Washington Barracks, D. C., and ordered to duty at Fort McHenry, Md. By Paragraph 13, S. O. 173, A. G. O., July 27, 1888.

GORGAS, WM. C., captain and assistant surgeon, U. S. A. Granted leave of absence for one month, to take effect on being relieved from duty at Fort Randall, Dak. Paragraph 4, S. O. 177, A. G. O., August 1, 1888.

EWING, CHARLES B., first lieutenant and assistant surgeon U. S. A. Relieved from duty at Fort Lewis, Col., and ordered to duty at Washington Barracks, D. C. By Paragraph 13, S. O. 173, A. G. O., July 27, 1888.

DEWITT, CALVIN, major and surgeon U. S. A. Relieved from duty at Fort Sully, Dak., and ordered to duty at Fort Missoula, Mont. Paragraph 5, S. O. 175, A. G. O., July 30, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING AUGUST 4, 1888.

HUDSON, A., medical inspector. Detached from the "Trenton" and ordered home.

WHITE, C. H., surgeon. Ordered to the "Trenton" via Panama.

URIE, JOHN F., assistant surgeon. Ordered to the Receiving Ship "Franklin."

BATES, N. L., medical inspector. Detached from the "Richmond" and to the "Pensacola."

ANDERSON, FRANK, passed assistant surgeon. Detached from the "Richmond" and to the "Pensacola."

KITE, ISAAC W., assistant surgeon. Detached from the "Richmond" and to the "Pensacola."

JONES, W. H., surgeon. Detached from the "Pensacola" and to the "Richmond."

STONE, E. P., assistant surgeon. Detached from the "Pensacola" and to the "Richmond."

MCCORMICK, A. M. D, assistant surgeon. Ordered to special duty in the Bureau of Medicine and Surgery.

WILBER, F. W. F., assistant surgeon. Reports arrival home having been detached from "Vandalia."

PEDUNCULATED PAPILLOMA OF THE BLADDER: SUCCESSFUL REMOVAL BY PERINEAL OPERATION.[1]

BY F. S. WATSON, M.D.

E. B., aged thirty-seven, was alarmed three years since by a very profuse hæmorrhage into the bladder. The urine, he said, was black with blood. This condition came on without any apparent cause. Ever since he has had intermittent attacks of hæmaturia. The urine sometimes has remained free from blood for several weeks at a time. Until very recently urination has been painless and natural as to frequency. He has had two or three attacks of retention due to the presence of clots in the bladder. Has often passed large clots, but never any fleshy bits until within a fortnight. He has lost about seventeen pounds weight during the last three years, but is still strong and in very good condition.

The urine at the time of his first visit contained bright blood in moderate quantity. Some pus, two or three small phosphatic concretions, which he had noticed for the first time in the preceding day or two, and a good many small shreds, which, microscopically, were seen to be the most typical examples of a benign papillomatous growth.

Rectal examination gave a slightly greater sense of resistance of the bladder wall to the finger over a small area just above the right lobe of the prostate. There was also tenderness on pressure at the same point. This was interesting to me, as it has been generally stated that unless cancerous these growths could not be detected by touch in the rectum. Nevertheless, I have been able to locate the growth exactly, previous to operation, in this case, and in one which I operated upon by the supra pubic method last summer by rectal touch. In the former case the growth was small and delicate. Dr. Cabot confirmed the observation in that instance. Bimanual examination was negative.

On April 23d, with the assistance of Drs. J. W. Elliot, H. W. Cushing and R. Lovett, I performed the perineal operation. Opening the membranous urethra on a grooved staff, the prostatic urethra and vesical orifice were rapidly dilated to admit the forefinger, which, upon entering the bladder, came at once upon a villous tumor, whose free surface was about the size of a small tangerine orange. It was attached to the bladder by a pedicle about one-quarter inch in length, and of the breadth of the forefinger, just above the right lobe of the prostate as per diagram. After some difficulty the pedicle was seized with a strong pair of curved forceps and twisted and chewed off, the larger portion of the tumor, which I show here, coming away in one piece. The stump of the pedicle and a smaller part of the tumor which remained behind were removed with curettes. Hæmorrhage was free during the operation. The bladder was washed out with a hot solution of boracic acid four per cent.; and this perineal drainage-tube (of which I will speak in a moment) was tied into the bladder. The operation was long and tedious. The patient had delayed reaction, the pulse being very weak and 120 for twenty-four hours afterward. Bleeding continued to be steady and free for twenty-four hours, then gradually diminished, *ceasing entirely on the third day.* Vesical tenesmus was frequent and severe for twenty-four hours, due to large clots plugging the orifice of the tube. Throwing an ounce or two of boracic solution into the bladder dislodged them, and relieved the patient at once until another one came into the tube.

Since the first twenty-four hours this patient has declared that he never felt better in his life. There was no rise of temperature, except for a few hours one week from the date of operation, due to a slight epidydimitis. I removed the perineal drain on the fourth day. He was moved from bed to couch on the fifth day. The urine is entirely free from blood, and only contains a very little pus, which comes from the prostatic urethra. Frequency of urination, once in four or five hours; and he can hold it all night. The perineal wound is nearly healed, and recovery may be said to have practically taken place in ten days from the date of operation.

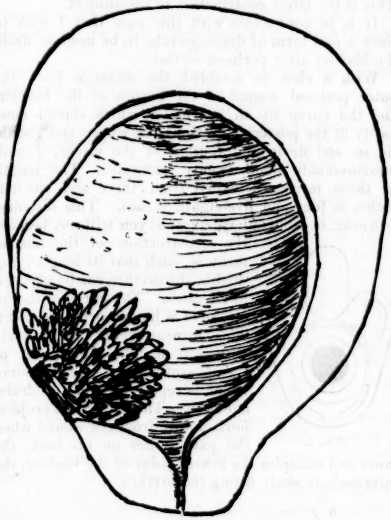

FIG. 1.

Three months have elapsed since reporting this case, and at this date of publication the patient is entirely free from all symptoms, and perfectly well.

In the last patient from whom I removed a tumor of the bladder I chose the supra-pubic route. The patient made an excellent recovery in nine weeks. I contrasted, then, the two operations, and pointed out their relative advantages and disadvantages, which I will not repeat now, but would only add that the operation should be selected according to the nature of the tumor as seen by the cystoscope, or felt by digital exploration through the perineum.

In those cases in which the growths can be removed by the perineal route I believe it is best to do so, as being less dangerous, and securing a shorter convalescence. If they are found to be too difficult to remove thus, the supra-pubic operation should be proceeded to at once.

[1] Read at the meeting of the Surgical Section of the Suffolk District Medical Society, May 8, 1888.

The perineal operation I consider much the more delicate and difficult.

In connection with the diagnosis of these cases, it is of interest to refer to a series of fifteen published in the *Lancet* of April 21, 1888, by Dr. Nitze.

The diagnosis was very accurately established in all by the cystoscope of Nitze, which Dr. Newell showed to this Society earlier in the year. In two of the cases hæmorrhage, although considerable, did not prevent a good view of the growths. The use of this instrument will, in all probability, render the employment of the other means of diagnosis which we have hitherto relied upon, unnecessary in many instances.

In eight of these cases the tumor was extirpated. In five the operation resulted in cure. One died from extension of malignant disease. In seven the supra-pubic method was employed. In one (a female) the tumor was removed through the dilated urethra. The operations were performed by different surgeons. This is the latest contribution to the subject.

It is in connection with this case that I wish to show a new form of drainage-tube to be used to drain the bladder after perineal section.

With a view to establish the distance from the outer perineal wound to the bottom of the bladder, and the curve of an instrument which should most easily fit the posterior urethra, and whose end should lie in and drain the bottom of the viscus, I took measurements upon twenty cadavers. The length in those measured varied from three and one-half inches to four and five-eighth inches. This distance, however, became unimportant, as you will see, because the construction of the instrument is such that its length lying within the urethra can be adjusted to all cases. The curve of the instrument is its important element. The measurements were made with soft metal. The result of the measurements gave the curve which is represented in this drainage-tube. The outer end projects horizontally from the wound when the patient lies on his back, the inner end occupies the lowest point of the bladder, the intermediate shaft fitting the urethra.

FIG. 2.

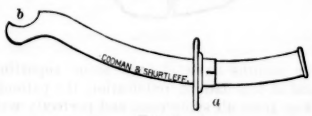

FIG. 3.

To complete the instrument it was necessary to have a plate attached to the tube by which to fasten it to the body, which could be pushed forward or backward on the tube according as the distance from the wound's surface to the bladder should vary in each case. This, as I have said, makes the difference in this distance in each case unimportant, and accommodates itself, also, to the extra length in cases of hypertrophied prostates. Accordingly, I had a plate fitting the perineum placed on the tube. The chief point in the successful construction of the instrument lies in a collar (*a*) of the depth of one-quarter inch, which projects from the front surface of the plate and embraces the tube, so that ordinary pressure will not force the plate backward or forward along the tube, but it *can* be adjusted at a longer or shorter distance from the end of the instrument by firm pressure, and will remain wherever placed. In this way the varying lengths of the canal to be traversed by the tube can be met at once by the instrument, the placing of the plate at any given point in the course of the tube being all that is necessary to make a longer or shorter drainage-tube, the flow of water from the tube on its being passed into the bladder being the guide as to the point on the tube at which to fix the plate. Tapes led through slots cut in the four corners of the plate (Fig. 2) attach it to a band going round the waist, and hold it in place. A rubber tube attached to the outer end of the gutta-percha drain leads the urine into a urinal.

The tubes are designed to be of various calibres to meet different indications. The one used in this instance was 34 (French). In case of hæmorrhage some of the tubes are supplied with a raised flange just above the eye (*b*) so that they can be converted into a canula *à chemise*.

The question as to the employment or non-employment of drainage-tubes after perineal section is often discussed and contrary views expressed. My own belief is that they are sometimes useful and sometimes not. Previous to this I have watched two cases after removing tumors of the bladder. No perineal drainage was supplied in one, and insufficient drainage in the second. The vesical tenesmus in both was excessive and painful to watch, and was entirely referable to the presence of blood-clots. In this last case I was enabled to relieve the tenesmus almost immediately by washing the clots out of the tube, and keeping the bladder empty.

I feel no doubt as to the desirability of using a large drainage-tube in cases where free hæmorrhage is to continue (as it almost always does after the removal of vesical growths) for, at any rate, twenty-four or thirty-six hours, or until the bleeding decidedly lessens; then it may be removed with advantage. The employment of such drainage-tubes are also indicated generally for a longer period after perineal prostatotomies, where it is desired to keep the wound open, a fact demonstrated and emphasized by Mr. Reginald Harrison. After operations for deep stricture the use of a drain through the perineal wound for a day or two has seemed to me to diminish the chances of constitutional disturbance, but here the tubes of smaller diameter will answer better. It is hæmorrhage into the bladder that calls for the larger sizes, and that, of course, is especially liable to occur after removal of new growths, or in rupture of the viscus. The tubes are, as you see, made of polished hard rubber, with rounded ends and very large eyes, and ensure the largest interior calibre, together with the thinnest possible walls.

— The editor of a Western journal made a pathetic appeal on behalf of the condemned murderer Maxwell. Among other things he said: "God knows that the picture of that mother and sister hovering like *angles* about the prison bars is enough to move a heart of stone, but more particularly considering the medical aspects of the affair I think the governor should interfere in behalf of the condemned Maxwell." How do Prellar's relations view this angular movement?

TWO CASES OF INCISION INTO THE HIP-JOINT, WITH OBSERVATIONS AS TO "DISTRACTION" IN HIP-DISEASE.[1]

BY E. H. BRADFORD, M.D.

THE writer wishes to place upon record two cases of direct incision into the hip-joint at an early stage of hip-disease, done for the purpose of checking the night cries, which were exceptionally severe (fourteen and fifteen times during the night), and which other measures had failed to control. In both of the cases it was supposed that the joint contained pus within a resistant joint cavity. In one of the cases, a girl of six, the incision was not perfectly done, and gave incomplete drainage, and no benefit was obtained by the procedure. The "night cries" gradually subsided, and the patient eventually made a good recovery, which was not retarded though not aided by the incision.

In the second case, a boy of four, a small quantity of thick pus was evacuated and the patient's symptoms decidedly relieved, but not until a short time after the operation. Two weeks after the operation the night cries had diminished so that they were not present, or only occasional, while before they had persisted for weeks at a rate of fourteen and fifteen cries a night. The immediate effect of the operative interference appeared not to be beneficial, and the sensitiveness of the joint was increased for a few days; but as soon as drainage from the joint became well established, and compresses and pads and bandages incidental to aseptic dressings were discontinued, the night cries diminished noticeably. No difficulty was encountered in opening the joint. A straight incision was made behind the trochanter major, extending above it. After the skin and muscles were divided and separated, the forefinger was thrust down to the joint and used as a director, the capsule was reached at the upper and back part of the joint. This was opened and the opening dilated. No distension of the capsule of the joint could be felt, and but a small quantity of thick pus was evacuated. The capsule wall, however, was found to be comparatively soft. After a slight pull upon the limb the femur was pulled away from the acetabulum and the finger could be inserted between the acetabulum and the head of the femur; both were found to be covered with granulations. No explanation could be found for the persistent night cries. The incision, etc., were done under aseptic precautions. The treatment after the operation was the same as before; namely, fixation by means of a fixation frame, and extension by an extension splint, and at the end of three weeks the boy was allowed to walk about on his crutches, elevated shoe, and wearing his extension splint.

It cannot be claimed that the amount of benefit obtained in these cases warranted the operative interference. For even in the second case perforation of the capsule and relief of the intra-capsular tension, and consequent extreme sensitiveness would have taken place spontaneously, and in all probability the drainage from the joint would have been better than that at first afforded by the incision. In the second case, however, relief of the symptoms was obtained somewhat more speedily after the incision than if left to a natural course.

In a large majority of cases the night cries are readily checked by extension and fixation. It seems reasonable to explain the exceptional cases where relief is not obtained in this way on the supposition that the joint, as in Case II, contained pus within a firm and resistant capsular wall, and that the bone of the femur and acetabulum are sensitive on undue pressure caused by reflex muscular spasm, secondary to the increased tension in the joint cavity.

In some instances the hypersensitiveness may be due to an abscess of the epiphysis of the head of the femur, and relief obtained, as has been shown by Macnamara, by perforating the head of the femur. Such cases, however, must be exceptional in children. It is possible that stretching the sciatic, as recommended by Macnamara, thus temporarily paralyzing the muscles and preventing spasm, may afford relief in extreme cases. But it would appear that less radical procedures were more practicable, and that we are to look to a perfection of "distraction," that is, mechanical separation of opposing bone surfaces of the joint as the most practicable method of relief. It has been denied that this, that is, distraction, is possible, but the frozen section of the case of hip disease reported by Lannelongue (the subject having been frozen with the affected limb pulled upon) demonstrates that distraction actually takes place.

If in an adult cadaver with normal a hip-joint, the muscles having been divided, the limb be pulled upon in a direction parallel to the axis of the body, it will be found that distraction does not take place. If in a fœtus of full term it will be found that it does. In Case II here reported, the fact of "distraction" could be readily determined. When the finger was placed upon the head of the femur it was found to be impossible to push it between the head of the femur and the acetabulum, the two bone surfaces being in contact. If, however, the limb was pulled upon by a force estimated at five pounds, the bones separated, and the finger could be readily inserted between the rim of the acetabulum and the head of the femur, the separation being about one-quarter inch. If the pull was discontinued the finger was caught by the opposing bones, and pressed upon with noticeable pressure.

In another case, a boy of nine, with hip disease, where a periarticular abscess was incised, the same observation was made, and the femur readily distracted from the acetabulum.

Through the kindness of Professor Dwight and Dr. Conant, of the Harvard Medical School, a number of normal adult hip joints were examined to determine the causes of the resistance to a distracting force.

It would appear that the chief cause of resistance was the cotyloid ligament, which in a normal adult hip is practically a cartilagineous collar holding the head of the femur in a tight socket. Direct pull on the femur in the line of the axis of the body causes the head of the femur to come in contact with the resistance of this non-elastic collar, and also encountering the resistance of the Y ligament. If the limb is slightly flexed and abducted, the femur can be pulled away from the socket if a fair amount of force be employed, showing that the influence of atmospheric pressure is not as great as has been supposed. If the limb is adducted it will be found that a pull in the line of adduction will bring the femur against the lower rim of the acetabulum.[2]

[1] Read at the meeting of the Surgical Section of the Suffolk District Medical Society, May 8, 1888.

[2] The experiments were made on dissected alcoholic specimens, where the knee-joint had not been opened, and with the capsule intact.

In young children, (it is to be borne in mind), the cotyloid ligament is not as strong or as developed as in adults, and the acetabulum is much smaller, the bony rim of adults being cartilagineous in children. It is also true that in tuberculous osteitis in the hip, as in other joints, the cartilages and ligaments at an early stage become softened and incapable of resisting a distracting force. Where the head of the femur has been absorbed and no anchylosis takes place, distraction occurs from a slight force. The direction of force in which distraction encounters the least resistance in a normal limb is with the limb slightly flexed and adducted.

FIVE CASES OF PERINEAL SECTION WITH EXCEPTIONAL COMPLICATIONS.[1]

SERVICE OF DR. C. B. PORTER,
Surgeon to Massachusetts General Hospital.

REPORTED BY DR. A. K. STONE.

CASE I. — CURETTING THE BLADDER FOR CHRONIC CYSTITIS.

J. A. W., aged forty-seven.

November 5, 1887. For the past seven months the patient has been extremely troubled with frequency of micturition. During the day he passed urine every fifteen to twenty minutes, and at night the intervals were never longer than one hour. At times he has severe vesical tenesmus, when he is obliged to keep his penis in a urinal for hours at a time, on account of the constant drizzle of urine. Before micturition there is pain, referred to the end of the penis. At times this pain runs backwards along the course of the entire urethra. Blood-clots have been frequently passed, and the urine contains abundant sediment, with shreds of so-called mucus.

Urine is pale; slightly alkaline; specific gravity, 1013; albumen, trace; sediment considerable; normal blood; little pus; numerous small round cells; crystals of ammonic urate.

Examination by Dr. Porter under ether. No stricture; no enlargement of the prostate; no stone in the bladder.

For the next three weeks the patient's bladder was washed out from time to time with boracic acid solution, 1 to 150. The bladder was extremely intolerant, and the introduction of the catheter always set up violent tenesmus and caused great pain. Only about one ounce of the solution could be injected before still more severe contractions would be excited, and the wash fluid expelled with violence. The tenesmus would continue several hours after the catheter had been withdrawn. Urine still contains pus and mucus and a trace of albumen.

As the patient had made no perceptible gain during his three weeks' stay in the Hospital, Dr. Porter decided to drain the bladder, and for this purpose, on the 26th of November, performed perineal section in the usual manner. After the bladder had been opened, the surgeon's finger was introduced into the bladder, which was found to be firmly contracted, even under ether. The walls were velvety, as if covered with exuberant granulations. The entire surface of the bladder was then thoroughly curetted and washed out, first, with corrosive sublimate (1–5000), then with hot phenyl (sulpho-napthol). A chemise canula was tied in. In the afternoon the patient had intense pain, which was relieved by washing out the bladder and removing a number of blood-clots. A rubber tube was substituted for the canula.

Five days later, the record says that the patient has been very comfortable and has slept well. His urine contains no blood. The drainage-tube was removed from the bladder twenty-five days after the operation. The urine came about equally by the penis and through the perineal wound. The patient at once regained control of the sphincters of the bladder, and, instead, passing urine every fifteen or twenty minutes, as he did before the operation, the intervals were about one hour's duration. Three days after the tube had been withdrawn, there came an increase in frequency of micturition, accompanied by pain and tenesmus in the rectum, which was not relieved by free catharsis. Examination of the rectum showed an abscess of the prostate, which was opened and drained into the rectum. The rectum was packed with iodoform gauze, which was removed two days later. The rectum was then washed with hot phenyl twice a day.

From that time on the patient steadily gained in flesh and strength. For a few weeks the bladder was washed out every day, but now with very little pain or discomfort. Almost all the urine is passed by the penis. For a day or two all will be passed by the penis: then, for a few days, a little will come by the perineum. The urine is clear and contains no pus. The intervals between micturition are now two hours to two and one-half hours during the day; while the patient sleeps nearly all night, passing his urine but once or twice. There is a slight stinging sensation after each micturition. On the 6th of February, fourteen weeks after entrance, no urine having come by the perineum for six days, he was discharged.

Remarks. This case shows how tolerant the bladder may be of even severe operative interference. The idea of curetting the walls of the bladder was forced upon the surgeon by the nature of the case. It was an emergency of the operation, and had to be met and settled at once; and the wisdom of the decision is clearly shown by the after-history. I have been able to find no similar case recorded in the "Index Medicus."

NOTE.— Patient reported July 3, 1888. Has gained twenty pounds in weight. Is able to do a full days work without any discomfort from frequency of micturition. Never has to get up more than once during the night to pass urine and usually holds it all night long. No perineal fistula.

CASE II. TUBERCULOSIS OF THE MEMBRANOUS PORTION OF THE URETHRA, RESULTING IN STRICTURE AND URINARY INFILTRATION.

O. C., aged thirty-two, box-maker, New Hampshire.

Patient has a good family history, and his previous history, up to six or seven years ago, has been good. He denies ever having a gonorrhœa or other venereal disease, and he never received any blow or injury in the perineum. Six years ago he began to have pain, starting in the small of the back and passing downwards and forwards towards the bladder. This pain was described as being like a pleuritic pain. The pain finally settled in the bladder and was very severe, and increased by any sudden movement or jar. Four years ago he had a swelled testis, and about the same time he began to be troubled with difficulty of micturition. The urine contained blood and considerable

[1] Read at the meeting of the Surgical Section of the Suffolk District Medical Society, May 8, 1888.

sediment. At times he has passed small particles, possibly of phosphatic nature. None, however, have been passed lately.

Such has been the condition up to four months ago, when he was taken one night with partial retention, being able to pass urine only in drops. Later, there was complete retention, and the urine had to be withdrawn with a small silk catheter, which he was taught to pass himself. Passage of this instrument caused considerable irritation to the urethra, so that for days he could pass his urine only in drops.

About eight or nine days ago a swelling appeared in the perineum. This tumor was finally opened by his physician and pus evacuated, and soon after urine began to escape by this opening. Since that time urine has come both by penis and perineum.

Patient is pale, emaciated, and very weak. Heart and lungs negative. Micturition about every hour. Urine of normal color; specific gravity, 1010; albumen, ¼ %; much sediment; much mucus and pus; bladder-cells in excess.

January 9th. Operation by Dr. Porter, under ether. Strictures, one three inches from the meatus, and one in the deep urethra, divulsed. A grooved staff was then passed, and the urethra opened through the perineum. The old fistulous tract was curetted. Deep down in the perineum a large amount of cheesy material was found; also a tract running off towards the left buttock, which discharged a thin, watery pus. The entire fistulous tract was laid open and thoroughly curetted. A catheter was tied in, and the wounds packed with iodoform gauze. The cheesy material was examined by Dr. W. W. Gannett, and the giant cells of tuberculosis found.

Eighteen days after the operation the catheter was permanently removed. It had worked perfectly during this time, and given the patient very little inconvenience. Urine then came entirely by the perineal wound. The patient has suffered but little pain, but is weak and miserable, and has a very poor appetite. He was given cod-liver oil and iron.

Ten days later the patient sat up for a short time in a wheel-chair. General condition is about the same. The urine is all passed by the perineal wound.

Two weeks later the patient was discharged at his own request. The patient has been up each day in a wheel-chair, and has grown decidedly stronger; eats and sleeps much better. The wound is still indolent, and shows little inclination to close. Sounds have been passed from time to time, but the urine is still passed by the perineum.

Remarks. The only gain for this patient was ability to evacuate his bladder without pain. It is of interest on account of the non-venereal history and the discovery of the giant cells of tuberculosis which in all probability were the source of all the trouble.

Case III. Extravasation from Stricture at the Meatus.

January 5, 1888. J. C. S., machinist, aged sixty-two.

The patient has had a stricture for twenty years. Several times in the last few years he has had retention, which would last for several hours. At the end of this time a plug of mucus would be passed, and the urine would then flow freely. No instruments have ever been passed. For the past few months the size of the stream has been gradually growing smaller and smaller. There has been some cystitis. The meatus has been very small, and at times has had to be probed with a needle to enable the patient to start his urine.

Last night the patient found himself unable to pass any urine. However, he suffered no special discomfort, passed an easy night, and kept about his work until noon to-day. At this time he noticed that his scrotum was beginning to swell, and he began to suffer both from the distension of his bladder and of the infiltrated tissue.

Patient entered the Hospital at 8 P. M. in great pain and distress. Temperature 103°, pulse 112 and intermittent. The bladder was as high as the umbilicus. The scrotum was as large as a child's head and very tense. The penis was much swollen and distorted. The glans was not visible, and the urine dribbled through the long, œdematous foreskin.

Operation by Dr. Porter, under ether. The scrotum was divided along the median raphé, and considerable bloody urine was evacuated from the tissue. The foreskin was then split upon the dorsum. The meatus was found to be practically closed, and would not admit even the finest filiform bougie. With some difficulty, a meatus was made. Then a filiform bougie was passed as a guide to the divulsor. Strictures were shown to exist both in the penile and deep urethra. After the divulsor had been passed, it was found impossible to introduce a No. 12 gum-elastic catheter. A Gouley staff was passed upon a filiform guide, and upon this staff perineal section was performed. A large quantity of ammoniacal urine was then drawn from the bladder. The bladder was washed with corrosive sublimate (1–5000), a catheter was tied in, and the wounds packed with iodoform gauze.

The patient reacted quickly after the operation. His pulse steadily improved, and he suffered practically no pain or discomfort. The wounds soon cleared and then began to granulate rapidly.

Three weeks after the operation the catheter was left out. The patient then passed all his urine by the penis. Four days later sounds were passed. These caused the patient considerable pain. That night he had a chill, and was very miserable for two or three days.

Four weeks and a half after the operation he sat up, and on February 13th, thirty-eight days after entrance, he was discharged. The only difficulty remaining was a granulating cleft in the scrotum. There was no pain or scalding on micturition, and no urine was passed by the perineal wound.

Remarks. Though there were other strictures besides the one at the meatus, yet this seemed from the history to be the one which was the cause of the trouble. The extravasation probably took place in the deep urethra at the weakest portion, and it was probably this spot that caused the inability to pass a catheter during the operation.

Case IV. Traumatic Rupture of the Urethra: Hæmorrhage Eighteen Days Later.

G. D., aged nineteen, mechanic, Haverhill, Mass. January 23, 1888.

Five days before entrance the patient fell down an elevator-well, striking astride a beam. For two or three days he was able to pass his urine in small amounts, but only with great difficulty and pain.

For the first day after the accident there was blood in the urine. Two days ago his urine stopped. An attempt was made to introduce a catheter, but without success. However, upon the withdrawal of the catheter, the urine came freely. Last evening it became necessary to aspirate the bladder. The patient entered with his bladder dilated to the umbilicus, and having passed no urine since the aspiration. His scrotum and perineum and buttocks were much bruised and ecchymosed.

Under ether, Dr. Porter, first having cut the meatus and keeping the beak of the catheter against the roof of the urethra, was able to introduce a gum-elastic catheter with ease. The catheter was kept in place for a week, and during this time the patient suffered no special inconvenience. On removal of the catheter, there was no difficulty of micturition, except a slight scalding.

Three days later sounds were passed. These gave no inconvenience, and the patient was up and about the ward and expecting to go home the following day, when he complained of general "bad feeling" on the morning of the third day after the passage of the sounds. In the afternoon he had a slight urethral hæmorrhage, which was controlled by ice. The next morning a catheter was again tied in. This caused considerable discomfort, and was removed on the following morning, and the bladder washed out with boracic solution. During the next half-hour the patient passed about a pint and one-half of blood by the urethra. He became quite blanched. There was a tumor in the perineum. Dr. Porter at once decided to do perineal section. After etherizing the patient, a staff was passed into the bladder and perineal section performed. A large clot was turned out from the perineal tissues, and in the midst of this infiltrated mass three spurting arteries were found and tied. A number of other small bleeding points were also secured. A catheter was tied in and the wound packed with iodoform gauze.

There was considerable difficulty in keeping the catheter in place and in running order, and from time to time the urine would break through the perineum, escaping from the bladder around the catheter. The catheter was removed in twelve days. The urine was then passed by the perineum. Ten days later sounds were passed, and after this the urine was passed partly by the penis and partly by the perineum.

Two weeks later only a few drops of urine escaped by the perineal wound. Bougies have been passed several times. There is still considerable tenderness in the anterior urethra.

Fifty-one days after admission patient discharged.

Remarks. The interest in this case lies in the fact that the secondary hæmorrhage took place eighteen days from the injury, and three days from any operative interference. In the meantime there had been no special pain or tenderness. There was no hæmorrhage after the vessels were once tied.

CASE V. EXTRAVASATION SHORTLY AFTER PASSAGE OF AN INSTRUMENT.

Longshoreman, colored, aged forty-five.

Patient had his first attack of gonorrhœa about twenty years ago, and has had some urethral discharge nearly ever since. Several times he has had fresh attacks, and several times chancroidal sores. For some years past he has noticed a gradual diminution in his stream of urine. Two years ago he had retention, which was relieved by catheterization. He was then given a catheter by his physician, and told to pass it every few weeks. For the past six months he neglected to do so, and during the latter part of this time his stream has been rapidly growing smaller and smaller. Night before last, he determined to try to pass his catheter. The catheter entered the stricture, which was about two inches from the meatus, and he tried to force it through, but was obliged to withdraw the catheter on account of pain. Some blood followed the catheter. The patient went to work the next morning. During the day his penis and scrotum began to swell, but he still kept at work. Next morning, after passing an uncomfortable night, things were still worse, and he sent for his physician, who advised his coming to the Hospital. This he refused to do until evening, when he entered at 8.30 P. M. Both penis and scrotum were extremely swollen, the penis measuring twelve inches in circumference.

Operation by Dr. Porter, under ether. The prepuce, which was nearly three inches in length, was laid open upon the dorsum. A filiform guide was then introduced with considerable difficulty through a stricture situated about two inches from the meatus. The divulsor staff was then passed, but the smallest-sized divulsor could not be forced through the tough, cartilaginous stricture. The staff and guide were withdrawn, and the scrotum and perineum were split in the median line and the urethra opened in the perineum. Through this opening a large amount of foul ammoniacal urine was withdrawn from the bladder. The divulsor staff was then passed from the perineal opening forwards, and the divulsor forced with great difficulty through the anterior stricture. The catheter was then passed and tied in. The skin of the penis was freely scored to allow the escape of urine from the infiltrated tissues.

The patient was comfortable on the next day, but on the second day had a chill in the afternoon, and the catheter was removed. Four days after the operation, the penis, which was still very large, began to slough. This was a decided surprise, as the dark skin had prevented any discoloration from showing, and everything appeared to be progressing favorably. The penis and scrotum were kept in phenyl poultices for the next two weeks. During this time large and very foul-smelling sloughs separated from the penis, leaving only strips of healthy tissue along the sides and underneath, and also the under part of the foreskin.

At the end of the two weeks the sloughs had all cleared off, and large granulating surfaces appeared between the strips of healthy skin. These strips were then turned upon the dorsum of the penis, so as to cover in as much granulating surface as possible. The long portion of the prepuce was turned downwards and backwards. The dressing is now done with ung. acidi boraci. The prepuce did not hold in place, but the strips materially aided in closing the granulating surfaces. The prepuce was then bound down with a strip of gauze, and after some time was made to adhere to the under side of the penis.

During the time that the sloughing and granulating process was going on the patient suffered intensely from erections. He would have them repeatedly the same night, and their frequency was unaffected by bromide or opiates.

The patient never passed urine by the perineal wound, but through an opening into the urethra at about the point of stricture, two inches from the meatus. After the passage of a bougie part of the urine would come by the meatus and part by the urethral fistula. The wound in the perineum had entirely healed; the cleft of the scrotum was granulating rapidly. The upper portion and sides of the penis had closed entirely, and the under portion was closing in.

At the end of eight weeks the patient was discharged, to return at some future time for operation upon the urethral fistula.

Remarks. In this case the anterior stricture was the only one present, and the urethra was ruptured just behind it. This accounts for the enormous infiltration of the penis.

The medical after-treatment of these cases was practically nothing. There was no call for diuretics, as the presence of the catheter in the bladder, or the relief caused by divulsion of the stricture, in some "reflex" manner seems to increase the flow of urine.

All the patients reacted quickly after the operations, and there was little or no call for stimulants. In only one case was there a chill soon after the operation. Here the catheter was promptly removed, and the patient given quinine. In three of the cases the catheter was retained for considerable time. There was no trouble from urethritis, and, indeed, so long as a catheter is in good running condition, patients at the Hospital seldom suffer any special inconvenience from its use. The catheter is held in place by a ligature tied about the catheter, and the ends are brought down along the side of the penis and held in place by a strip of plaster about an inch in width. A rubber tube, with a glass joint to enable one to tell at a glance whether or not the urine is running, is attached to the catheter and carried into a bottle which is suspended at the side of the bed. By this means all the urine is removed from the bladder by siphon. All wounds of this nature are packed after the operation with iodoform gauze. In a few days the gray sloughing condition disappears, and a dry, red surface remains. This condition will tend to remain if iodoform dressing is continued. If, however, the dressing is changed to a charpie dressing, soaked in balsam of copaiba, the granulations spring up almost immediately, and the granulation progresses much more rapidly than under any other dressing.

The only exception to be noted to this statement is in wounds in tuberculous subjects, and of this Case II is a good example.

TWO FORMS OF SKIN TUBERCULOSIS.

BY JOHN T. BOWEN, M.D.

As a result of the discovery of the tubercle bacillus, and of the greater precision offered to the diagnosis of tubercle by the histological advances of the last few years, attention has frequently been called to certain lesions of the skin, often obscure in their clinical appearances, which on pathological examination have proved to be examples of tuberculosis. Of late the examples have rapidly multiplied and a source of external infection has been demonstrated in many instances. Of especial interest as illustrating possible modes of infection, may be mentioned four cases observed in Billroth's clinic, and reported by v. Eiselsberg.[1] In the first case the patient, a girl of sixteen, presented on the lobe of the ear, a hard, reddish-blue, non-ulcerated nodule, which appeared after wearing a piece of yarn, passed through the hole made for earrings. The second case is of an ulcer of the upper arm developing from a stab wound. In the third case a woman, aged fifty, after scratching an acne pustule on the face, developed at this spot an ulcer with thin jagged border. At the time this lesion appeared the patient had been washing the clothing of a woman ill with tuberculosis. In the fourth case there appeared a fistula on the arm, with a bluish appearance of the surrounding skin, at the site of a subcutaneous injection of morphia. Patient was a girl of twenty. In all of these cases the lesion was excised, and the characteristic appearances of tubercle found, as well as the tubercle bacillus. Other cases could be enumerated where the infection was derived from animals, for example, that of a veterinary surgeon who received a wound while opening the body of a tubercular cow, from which followed a tuberculosis of the skin, tuberculosis of the lungs, and death.[2]

Most of these observations unfortunately offer us but little light to guide us to a clinical diagnosis; indeed, the diagnosis has not usually been correctly made before the microscopical examination, and the whole subject is at present surrounded with great uncertainty and confusion. Two forms have, however, been extricated from this confusion, which are believed by some to represent distinct clinical types of tuberculosis; namely, a miliary form, and secondly the verrucous tuberculosis, tuberculosis verrucosa cutis of Riehl and Paltauf. (Lupus, which in the present state of our knowledge must also be regarded as a form of tuberculosis, offers us in most instances well-defined points of difference from these two types.)

I. Miliary Tuberculosis. This form has been met with only in subjects affected with rapidly-progressive tuberculosis of internal organs. Chiari[3] reported the first case of this type, and was followed by Jarisch[4] with the report of a case where the probable diagnosis was made *intra vitam*. Since then cases have been reported by Riehl, Schwimmer, Finger, and by several French writers. Chiari examined 7,000 bodies, (of which about sixty per cent. were tubercular), with reference to these lesions, with the result of finding them in five cases only, all on the lower lip. These lesions are described as shallow ulcers, situated at the juncture of the mucous membrane with the skin at the entrance to the mouth, nose, anus and vagina, and also upon the ear. The edges of the ulcer are said to be characteristic, being moderately firm and made up of a succession of small, jagged indentations, having an appearance as if "gnawed," (ausgenagt). Miliary tubercles, in the form of yellowish-white, transparent nodules, can be seen in parts of the ulcer. These lesions are rapidly progressive, all changes occurring by a degeneration of the miliary tubercles, and by the confluence of the small ulcers. This form has been often referred to as representing a true tuberculosis of the skin, and has been cited as an argument against the tubercular nature of lupus.

A case undoubtedly belonging to this class came

[1] Wiener Med. Wochenschrift. 1887. No. 53.
[2] L. Pfeiffer. Zeitschrf. f. Hygiene. III Bd. s. 189.
[3] Wiener Med. Jahrbücher, 1877. 3 Heft, s. 328.
[4] Vierteljahresschrift f. Dermat. und Syph., 1879.

under the writer's notice in Vienna. The patient, who was far advanced in tuberculosis of the lungs, presented a shallow ulcer at the edge of the ala of the nose, and a similar one along the lower edge of the septum. These ulcers were very sensitive to the touch, having a jagged edge, considerably infiltrated. Antispecific remedies were tried, although tuberculosis was suspected, but with no influence on the lesion. Some time afterward, while studying in the pathological department, I discovered this patient on the autopsy table, and was able to obtain the lesions of the nose for microscopical study. The ulcers were unquestionably tubercular. Besides the usual appearances of a granulation tissue containing large epithelioid and giant cells, much cheesy degeneration was found, offering a marked contrast in this respect to the ordinary lupus. Examination by Ehrlich's method revealed the tubercle bacillus in abundance, a considerable number being found in every section examined.

II. Verrucous Tuberculosis. This includes the so-called anatomical wart, verruca necrogenica. That these anatomical warts, so frequently seen on the hands of persons working in dissecting-rooms and at the autopsy-table, were in reality produced by a local inoculation from tubercular virus, had been considered probable for a number of years, and was asserted by Besnier in 1883. Since then numerous observations, especially by the French, have shown the presence of tubercle bacilli in these lesions. In 1886, Riehl and Paltauf [5] described a form that they named tuberculosis verrucosa cutis, which was similar to the verruca necrogenica. Eleven cases had been observed up to that time, all of which occurred in persons having to do with animals or with animal products. Five of these patients were butchers, two cab-drivers, one wheelwright, one farmer, and two cooks. The affection occurs in patches on the back of the hands and fingers, and in both clinical and histological appearances is similar to the verruca necrogenica. The affection has been very carefully studied by Riehl and Paltauf, to whose article reference should be made for an accurate description. The following case presents so many points in common with this form, that it may, I think, be properly reported here.

I am indebted to Dr. W. F. Whitney for the material for microscopical examination, and to Dr. O. K. Newell, in whose practice the case occurred, for permission to report it. The patient was a carpenter, fifty-two years of age, who had had for about nine years a lesion of the back of the left hand, two centimeters long and one and one-half centimeters wide, situated over the lower end of the fourth and fifth metacarpal bones. It was described as a raised patch, of a bluish-red color, moderately firm, and of a slightly papillomatous appearance. Occasionally pustules would occur over limited areas of the affected region, breaking down into small ulcers. The lesion had been treated with caustics and in other ways, but without permanent effect. Its progress was very slow. No history of any previous affection could be ascertained which would throw light on this manifestation. The patient had been for a number of years, engaged in the carpentering work required for the shipment of cattle by transatlantic steamships, and was often employed in repairing quarters that had been occupied by cattle during transportation, although it is by no means certain that the lesion had not made its appearance before this period. The lesion was excised by Dr. Newell in 1885, the wound healed rapidly, and inquiry a short time since revealed the fact that there had been no recurrence, and that the man was enjoying his usual good health.

The diseased tissue that had been hardened in alcohol presented the appearance of a raised patch, of a more or less papillomatous character. Microscopically, the papillæ were found greatly elongated and covered with layers of horny epidermis, and at the same time there seemed to be a growth of the rete downward into the corium in many places. In the papillæ and upper portion of the corium lay nests of round and epithelioid cells, together with large bodies with nuclei at the periphery, corresponding exactly to the giant cells. In places a cheesy degeneration could be distinguished, although this was never pronounced. Beside this granulation tissue, purely inflammatory foci were present, seldom having reached the stage of suppuration. Sections stained by Ehrlich's method revealed the tubercle bacillus in the nodules of granulation tissue, in far less numbers than in the case of miliary tuberculosis mentioned above, but more numerous than in ordinary lupus.

This case, in its history and pathological appearances, corresponds pretty accurately with the tuberculosis verrucosa cutis of Riehl and Paltauf. In favor of this view may be urged the appearance of the lesion at an age when a first outbreak of lupus belongs to the greatest rarities; its clinical appearances and course; and the result of the microscopic examination, which shows a tissue undeniably tubercular, and which differs from that of lupus in the presence of bacilli in greater numbers, in the more superficial seat of the nodules in the upper layers of the corium, in the presence of cheesy degeneration, and in the appearance of foci of acute inflammation.

A case of this form of tuberculosis was reported last year by Finger, where the patient subsequently died from tuberculosis of the lungs, and Riehl exhibited this year a patient in whom gommes scrophuleuses and signs of internal tuberculosis had developed consecutively to this skin lesion.

As to treatment in these two forms, but little is to be said. In the miliary form, remedies have thus far proved of little avail. The patients are, as a rule, so far advanced in tuberculosis of internal organs that the skin lesion, although progressive and sometimes painful, becomes of secondary importance. For the verrucous form, radical treatment, either with the knife or cautery, is recommended. The usual practice in Vienna, for the last few years, has been thorough curetting, followed by cauterization with the solid stick of caustic potash. Less active agents, as salicylic acid, cause a diminution of the growth.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., BOSTON.

CONVERGENT STRABISMUS.

LANG and Barrett [1] report the results of the observations and treatment of 102 cases of convergent strabismus who were kept under observation for some considerable periods of time. The method of observation was as follows:

[1] The Royal London Ophthalmic Hospital Reports, Vol. xii, part I.

(1) The distant vision of each eye was tested with and without glasses.

(2) The power of fixation of each eye was tested.

(3) The movements of the eyes were examined, particular attention being given to the extent of the excursion outwards of the squinting eye.

(4) The angle of convergence was measured by a modification of Landolt's methods.

(5) The iris and ciliary muscles were completely paralyzed by atropine, or by homatropine with cocaine.

(6) The angle of convergence was again measured.

(7) The refraction was estimated by retinoscopy and the vision with the correcting glasses determined when practicable.

(8) The full correction was ordered for each eye, the glasses were obtained and worn, and then, and not till then, was the use of mydriatics discontinued.

(9) The patients returned at intervals of three to six months. At these visits they were examined with respect to — (*a*) The angle of convergence whilst the glasses were worn. (*b*) The angle of convergence when the glasses were removed. (*c*) The vision in each eye. (*d*) The presence of binocular or monocular vision as ascertained by the colored letter test.

(10) In those cases in which this treatment did not produce satisfactory results, the internal rectus was divided. The angle of convergence was measured immediately before and after the operation, and at the usual intervals of from three to six months. In no case were the two internal recti divided at the same time, and in a very few was it necessary to divide both. No other operative procedure was ever resorted to.

These 102 cases included no case of convergent strabismus from congenital or other paralysis of the sixth nerve. Their ages varied from four to thirty years, and there were included a few squinting myopic eyes, and eyes with corneal nebulæ. The spectacles ordered were usually large circular ones, the centres being adjusted for distant vision.

IMPROVEMENT BY GLASSES.

The cases under ten years of age were 61, in 53 of whom some improvement was effected and in 8 there was no improvement. The cases over ten years of age were 41, in 34 of whom some improvement was effected and in 7 there was no improvement. Of the cases under ten years of age the improvement was noticeable *only* while the glasses were worn in 15 cases, and in 10 cases over that age the improvement was not present when the glasses were removed. Taking all the cases together the improvement only existed whilst the glasses were worn in 25 cases, or 29.4 per cent., whilst improvement after removal of glasses existed in 60 cases or 70.6 per cent.

Of the 87 cases in which there was improvement, the average original convergence was 23.2° the average amount remaining whilst the glasses were worn 9.1° and the average amount of improvement 14.1°. Of the 60 cases in which there was improvement after removal of glasses, the average convergence was 23.8°, the average amount remaining without glasses 13.5°, and average amount of improvement 10.3°. The glasses were worn usually from six to twenty-four months. As a general rule the longer they were worn the greater was the beneficial result. This remark applies with greater force to those under than to those over ten years of age.

Cases of Cure.— Cases of cure whilst the glasses were worn, under ten years of age, were 27, over ten years of age were 10. Cases of cure when the glasses were removed, under ten years of age were 8, over ten years of age 3. Thus, out of 102 cases, 37 or 36.3 per cent. were cured so long as glasses were worn, and 11 or 10.8 per cent. were permanently cured. In most cases even of cure, monocular vision alone was obtained, when binocular vision was obtained it was usually only whilst the glasses were worn; on their removal it became monocular. Their conclusions are as follows:

(1) The spectacle treatment of convergent strabismus produces a rapid and complete cure in about 10 per cent. of cases.

(2) In a larger number (33 per cent.) the cure continues so long as the glasses are worn. In these cases it would probably become permanent in course of time.

(3) The effect of this treatment is in direct ratio to the youth of the patient.

(4) Spectacle treatment should therefore in the great majority of cases be adopted as an indispensable preliminary adjunct to any operative treatment. By this treatment there is no chance of producing the absolute divergence which occurs sometimes after tenotomy. Exceptional cases occur in which the treatment is inapplicable on account of the occupation of the patients.

(5) If the spectacle treatment fails to produce absolute cure, a division of the internal recti generally suffices, together with the use of glasses, to remedy the deformity. In some few cases the opposite internal rectus must be subsequently divided.

Professor Landolt's [2] method of proceeding in a case of strabismus is as follows: — The nature of the squint paralytic or concomitant, is determined; its degree is ascertained by angular measurement; the field of fixation is mapped out, at least in the plane of deviation; the amplitude of convergence and accommodation, as well as the refraction and the visual acuity are determined. If possible the date at which binocular vision was lost, should be ascertained, and also whether diplopia can still be produced by prisms, the deviating eye should be placed in as favorable a condition as possible by correction of the ametropia, the use of a colored glass before the other eye, etc. If the patient be young, every means at command which may diminish the squint should be used before proceeding to operate. In *convergent* strabismus, all work requiring accommodation for a near point should be stopped, the eyes atrophinized, the total amount of hypermetropia corrected, and, if possible, stereoscopic exercise regularly practiced.

Our means of remedying *divergent* strabismus without operation are less efficacious. Nevertheless, if the condition be due to general or local muscular weakness, tonic and gymnastic treatment may render good service. Professor Landolt continues: I never operate for strabismus until I am convinced that I have obtained all possible help from these methods of "pacific" treatment; and having done so, and having by their use reduced the degree of deviation, the operation most suitable to the remaining squint must be performed. Our operative procedures, no matter how skilfully we perform them, are so clumsy in compari-

[2] Archives d' Ophthalmologie, Sept.-Oct., 1887. Ophthalmic Review, Jan., 1888.

son with the delicacy of the functions of the ocular muscles, that if we trust to them alone we shall certainly meet with failure.

Simple tenotomy will not correct a *convergent* strabismus of 20°; and in such an instance there is a choice of two methods of treatment: (1) division of both internal recti; (2) division of the internal and advancement of the external rectus of the same eye. Landolt advises recourse to the former method if the squint be alternating, to the latter if it be constant. If, a few days after the operation some divergence be present, atropine should be relinquished and the patient allowed to use the eyes. The natural tendency to converge will then aid in restraining the outward deviation. When, in spite of this, the eye still deviates, a slight advancement of the tenotomized muscle is preferable to division of the tendon which has been readjusted. *Divergent* strabismus is much less easily dealt with, and more care should be taken not to produce an over-correction by operative means. Before deciding on the mode of treatment, not only must the degree of deviation be ascertained, but also the power of the abductor and adductor muscles. Examination of the field of fixation will often reveal a considerable limitation of the inward movement, and this not alone in the squinting eye. If the divergence be of low degree, for example, 10°, and the field of fixation reach at least 47° inward, a single tenotomy may suffice; if not, tenotomy of the external rectus of the second eye should be performed. In cases in which the divergence is of long standing and high degree, and the field of fixation is greatly limited inwards, tenotomy of the external, with advancement of the internal rectus is urgently called for; and it may be necessary, in order to complete the cure, to perform a similar operation on the second eye. Before having recourse to this second operation, the means at our disposal to increase or induce convergence should be tried. No atropine should be used; only the eye operated on should be bandaged if tenotomy have to be performed, and both eyes (when advancement of the muscle has been done) only for two days. The uncovered eye will then, during its movements, have the effect of inducing similar action in the muscles of its fellow.

THE RETURN TO THE FLAP OPERATION.

Schweigger,[3] in an article under the above caption after a review of the origin and history of Von Graefe's linear peripheric extraction with iridectomy, says: The tendency from the beginning was to make a larger incision. This was only possible by a return to the flap operation, and so sailing under false colors of linear incision, a gradually growing flap was used. Having been obliged by force of circumstances to return to the flap incision, the next question was whether the small knife was suitable for it. It was excellent where a small flap was needed, with a small anterior chamber, as in many cases of iridectomy for glaucoma, etc. If, however, it was necessary to make the flap larger than the width of the knife the incision could only be finished by a sawing movement. The most appropriate instrument, as demonstrated by G. A. Richter over one hundred years ago, is one where the mere passing forward of the knife finishes the incision, with the exception of a small bridge of tissue which is divided when the knife is withdrawn. The incision is no larger than that made with the small knife. It may, indeed, be made any size desired, while the advantage of a regular clean cut favoring cicatrization and the preservation of the curvature of the cornea quite is evident. For this reason he gave up the use of the small knife for cataract operations about a year ago, and commenced using a knife which was 5 mm. wide at a distance of 30 mm. from the point. He soon, however, recognized the advantages of the old cataract knife, and used first one 6 mm., and finally one 7 mm. Since then he has done all extractions of cataract senilis with the triangular knife, with a flap about 4 mm. high, gradually omitting iridectomy, at first in well-chosen cases, and later more often. With a flap 4 to 4.5 mm. high there was not the slightest difficulty with the iris. If a few pigmented points are brought away with the cataract it is not of much consequence.

Then the important question arose as to whether the danger of prolapsus iridis in the classical operation was really so black as it was painted, and the more he studied this point the more it seemed to him that its dangers had been exaggerated. In sixty cases of extraction, as described above, five only resulted in prolapse of the iris. Too large an incision is one of the causes to be avoided. It is desirable to have a clean cut; not too peripheral, but in the transparent cornea, on the anterior edge of the limbus. Conjunctival flaps may be omitted without disadvantage. With the escape of the lens there is almost always some prolapse of the iris, but it can easily be stroked back with a curette. Should, however, the iris be pushed into the wound by the pressure of the vitreous body, it is much better to do iridectomy at once. In sixty-two cases without iridectomy, prolapse of the vitreous happened but twice. Prolapse of the iris is not necessarily caused by this, for the vitreous body presses it backwards, especially if the hyaloidea does not tear directly behind the incision. Eserine should be dropped into the eye directly after the operation, and at the first change of the bandage perhaps. If used too long it favors iritis. The main point of the after-treatment is that any opening of the lid should be avoided. Eserine, atropine, etc., may be used without opening the eye. A contracted pupil it desirable for the first two days; after this mydriatics are necessary, as more than fifty per cent. of all cases heal with posterior senechia. If the first three days are safely passed over, there is no danger of prolapsus iridis, unless some unforeseen accident should take place. It is a remarkable fact that the forms of incomplete opacity of the lens, in which extraction is permissible at all, give just as good results if the extraction is done without as with iridectomy. The flap operation without iridectomy will regain its proper position, and for this we have to thank solely the introduction of cocaine.

Knapp[4] in an article upon the extraction of cataract without iridectomy emphasizes the following points. It is of importance that the flap be of sufficient size: for a hard, ripe cataract fully two-fifths of the corneal edge of the limbus conjunctival. A conjunctival flap is somewhat in the way during the operation, but it acts favorably upon the closure of the wound, and is a protection from secondary infection. The peripheric location of the corneal section does not in itself favor the occurrence of prolapse of the iris. The mode of expelling the lens differs from that used in the combined extraction. The pressure should be made

[3] Archives of Ophthalmology, Vol. xvi, No. 4.

[4] Archives of Ophthalmology, Vol. xvii, No. 1.

through the cornea on the lower portion of the lens directly towards the centre of the globe. In this way the flap rises, tilts forward, and the lens passes through the pupil with the least bruising of the iris. The removal of the cortex is done in the first place, by following up the escaping cataract with the spoon, continuing the pressure, so that, if possible, the whole cortex may come forth with the lens. The moment the lens is out, the speculum should be removed, and in case any remnants lag behind, they should be wiped out with the edge of the lower lid, care being taken that neither the edge of the upper lid or any other organic part, be passed through the wound. These pressing movements with the lower lid can be done boldly and without injury, are very efficient, and when they fail other means are not likely to succeed. During the operation the eye should be irrigated frequently with Panas' solution. In this series of one hundred cases operated upon in this manner, prolapse of vitreous occurred five times. In four of them the iris was pressed back. All got well without incarceration, and obtained good vision. Prolapse of the iris occurred in twelve cases; in four the prolapse disappeared spontaneously in the course of some months. In four others it was removed with scissors. In one, produced by a hurt, it was reduced two hours after its occurrence. No reaction followed and the pupil was clear and central. In two cases the prolapse remained. In eight cases the iris did not protrude but was more or less extensively united to the scar. Twenty times the presence of iritis or posterior senechiæ is noted. Cyclitis has not occurred at all. After secondary operations in necessary cases the results were 96 per cent. good, 3 per cent. moderate, 1 per cent. failure.

A NEW METHOD OF CORNEAL TRANSPLANTATION.

Von Hippel[5] in an article with the above title reviewing at length the history of corneal transplantation, concludes that the subsequent opacity of the transplanted portion of the cornea is due to the fact discovered by Leber that the transparency of the cornea depends upon the integrity of the epithelium lining Descemet's membrane, as the edges of that membrane after a transplantation are always found to have curled back from the cut edge and thus allow the entrance of the aqueous, and from this cause the graft swells and so becomes opaque.

The essential factor of our author's new method is that in trephining the leucomatous cornea he does not perforate but leaves Descemet's membrane intact, and upon this plants his graft.

In his first cases, which were failures, he attributes the cause to the fact that the graft taken from the cornea of a dog was cut in the same manner as the original piece removed from the leucomatous cornea and the difficulties of removal of the piece injured his graft. In his subsequent and successful operation, he chose a rabbit to take the graft from and trephined the whole thickness of the cornea and planted this on Descemet's membrane as before. In his successful case the vision was improved from counting fingers at two metres to $\frac{20}{200}$. His methods of operation are as follows:

(1) The lids being opened by an elevator he sets the trephine vertically upon the cornea and fixes the globe by two pairs of forceps. One to the inner and one to the outer side of the globe. Although cocaine is used for the anæsthetic there is always more or less bleeding from the cut in the leucoma.

(2) The removal of the trephined portion of the cornea is the most difficult portion of the operation, and is done in the following manner. The trephined portion is seized with a pair of strong, straight, iris forceps with sharp teeth, and dissected off with a Graefe cataract knife. The aim being to remove a piece of equal thickness and to leave the cut margins vertical. This step of the operation is much complicated by the hæmorrhage, and when done, a solution of bichloride is instilled, and the lid closed with gentle pressure to arrest the bleeding.

(3) With the same trephine a portion of the cornea of a rabbit, anæsthetized by cocaine is removed. A young rabbit is preferable on account of the thinness of the cornea. The fixation of the eye of the rabbit is a somewhat difficult operation and is best done by inserting a strabismus hook behind the eye around the nerve and drawing the eye as far out of the orbit as possible so as to press firmly against the lids.

(4) The graft is then laid upon the cornea near to the defect caused by the trephine and then slid with a spatula into the area of the wound. The transplanted portion must not project above the surrounding tissue or it is liable to be dislodged. As soon as the graft is in the proper position the whole cornea is dusted with a thin layer of iodoform, the lids closed, a bandage applied over both eyes, which is allowed to remain undisturbed for two or three days, and on the eighth or tenth day the eyes can be left opened, if all injection has disappeared.

Von Hippel's conclusions are as follows:

(1) The possibility of corneal transplantation by my method with the permanent transparency of the flap with a material improvement of the vision is undoubtedly demonstrated.

(2) Even in the case of leucomata which extend through whole thickness of cornea.

(3) It is impracticable in adherent and bulging leucomata.

(4) The operation is without danger and with very little pain to the patient, and so can be undertaken in all cases in which there is the least probability of a good result.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.

G. H. MONKS, M.D., SECRETARY.

Meeting Wednesday evening, May 8th, the Chairman, Dr. J. Collins Warren, presiding.

On motion of the Secretary, it was *voted* that a Committee of two be appointed by the Chair, who should assist the Secretary in selecting subjects for the meetings of next year, and in securing the services of those members who, in their judgment, should be best suited for the presentation of such subjects.

Dr. E. H. Bradford read a paper on

TWO CASES OF DIRECT INCISION INTO THE HIP-JOINT, WITH OBSERVATIONS AS TO "DISTRACTION" IN HIP DISEASE.[1]

Dr. W. M. Conant said: At the request of

[1] See page 147 of the Journal.

Dr. Bradford, I have brought before the Section a number of ligamentous preparations of the hip-joint, and will demonstrate them with special reference to the function of the cotyloid ligament as a means of holding the head of the femur in the acetabulum. It is hardly necessary to mention the ligaments of the hip, yet it may recall some forgotten points if I do so. The ligament teres connects the head of the femur to the acetabulum.

The cotyloid ligament surrounds the rim of the acetabulum and deepens it. Below the notch there is the transverse ligament, and over this the cotyloid extends, so that there is a complete circle of cotyloid ligament. This specimen shows that the outer edge of cotyloid extends beyond the head of the femur, so that its outer margin grips the constricted portion of the femur just below the head, when it is pushed into the bottom of the acetabulum. Then there is the capsular ligament, which surrounds the joint, and this is strengthened in front by the ileo-femoral or Y ligament. This ligament extends from the inferior anterior spine of the ilium to the anterior trochanteric line, and is put on the stretch when the body is in the erect position. This ligament is very strong, and serves as a check to hold the femur in position when the body is erect.

It will be noticed that the head of the femur is not a perfect circle, and that the longest diameter is from superior portion of the head to the inferior portion at the neck. This makes evident the fact that in certain positions the longest diameter of the head might impinge upon the cotyloid ligament, so that the amount of distraction on separation of the head would be very slight.

This specimen shows that with the femur extended the longest diameter of the head impinges on the cotyloid. It may be said that the Y ligament holds the head because it is on the stretch; if, however, this is cut, there is still very little distraction. But if you flex the femur, the shorter diameter of the head now impinges on the cotyloid, and on pulling there is more distraction. If, now, I abduct the femur, as well as flex, you have the shortest possible diameter against the cotyloid, and on using force it is possible to get very considerable distraction.

If you pull down with the femur in the line of the body you get almost no distraction, but as soon as you flex and abduct the head of the femur comes out with very little difficulty, and can as easily be put back into the acetabulum.

DR. CHEEVER: The difficulty of draining the hip-socket, I should think, would be very great. In former times I frequently excised the diseased head of the bone, and even then was so struck with the difficulty of draining and washing out the cavity, that I adopted the practice of cutting a large triangular flap of skin and muscles, and sewing it or pinning it back, thereby converting the cavity of the acetabulum into an open crater or saucer, which could not close up. The depth of the parts, the thickness of the fasciæ, and the contractions of the muscles, I should think, would render drainage into the hip, which was incised by any ordinary incision, almost impossible. I had an idea that the benefit derived from extension was not so entirely by drawing the diseased surfaces apart, but was also by holding the muscles absolutely still, so that, being tired out, they did not give spasmodic contractions on the slightest nervous provocations. However it may be, the fact remains that in the majority of cases of hip disease, unless acute abscess is forming, extension almost always gives relief.

DR. WHITMAN: I understand, then, that Dr. Bradford recommends extension with abduction in these cases, considering the fact that the leg can be more easily extended when abducted.

DR. BRADFORD: Yes, in certain cases. In adults it is evident that extension in the line of the body does not cause distraction; that is, separation of the bones. In children, of course, that is not as true, because the cotyloid ligament is not so firm and the acetabulum not so large as in adults. In all probability it is not necessary to abduct the leg, but in extreme cases, such as I referred to to-night, I should say that extension in the line of flexion and abduction would give better distraction than the ordinary way.

DR. BRADFORD: In regard to the drainage of the hip-joint, I think that Dr. Cheever is certainly right that it would be practically impossible to drain the hip-joint thoroughly by a simple incision. In the case that I reported, the second case, I did not expect to entirely drain the joint. What I did expect, however, was to cut down upon the joint that was distended by pus, and allow the escape of that pus by incising the resisting wall of the capsule. I accomplished it in a measure, but I don't think I accomplished it as thoroughly as it could have been done, and I did not find the joint as distended as I expected to. There was not more than half an ounce of pus in the joint. I think that Dr. Cheever has expressed the object of extension exactly: that it is not only to cause distraction, but also to counteract the spasm of the muscles. I laid stress upon the subject of distraction because it is a matter which is to a certain extent under discussion, and it seemed to me important to show that distraction could be carried out.

DR. J. W. ELLIOT showed Bozeman's apparatus for

DRAINAGE OF THE BLADDER THROUGH THE VAGINA,

and explained its construction and action.

DR. A. K. STONE reported

FIVE CASES OF PERINEAL SECTION WITH EXCEPTIONAL COMPLICATIONS[2]

occurring in the practice of Dr. C. B. Porter.

DR. PORTER said: It is not my custom to report my cases at a medical meeting by proxy, but these cases had been carefully prepared for publication in the JOURNAL by Dr. Stone, and at the request of the Secretary of the Section he consented to read them here to-night. The case of curetting the bladder interested me very much on account of the peculiar condition of the mucous membrane, which felt like exuberant granulations, covering the whole surface, the bladder being firmly contracted, and I said at the time of examination: "If this were anything else, I would curette it." And then I thought at once: "Why should I not do it, under the circumstances?" By a pressure above the pubes the whole bladder was readily brought into relation with the curette, and its whole internal surface was cleaned just as an epithelial ulcer on the face would be scraped. The after-progress of the case certainly proved that the treatment used was the best thing that could have been done. From passing urine every fifteen minutes,

[2] See page 148 of the Journal.

and from its being nasty and bloody, it very soon came away clean, and the patient went from the hospital holding the urine very much better, and rising but once or twice in the night.

The case that proved to be tuberculosis was exceedingly interesting to me, because it was a complication which I did not expect. The man was in a pasty, waxy condition, but I did not think that he looked worse than a great many cases that present themselves with stricture, with an abscess in the perineum or perineal fistula, and I think that it was not so much the stricture produced by gonorrhœa which caused the obstruction, as it was the swelling of the parts about the urethra, and the involvement of the urethra by the deeper deposit. I did not suspect the tuberculosis until I saw the cheesy deposit as it appeared under the knife.

The case, where there was a traumatic rupture of the urethra, was interesting to me from the fact that the man had very little hæmorrhage, if any, from the urethra, until the eighteenth day. And that was after he had been free from his catheter for a number of days, and sounds were passed merely to insure the patency of the urethra, in order that he might be discharged, he being practically well, and there being no swelling and no soreness. The ecchymosis had almost entirely disappeared. Then, supervening on that was this very sudden hæmorrhage, so that while I was making the visit in the morning, being absent from the room perhaps half an hour, the patient bled a pint and a half from the urethra; and that without any previous manipulation, with the exception of a catheter in the urethra. Then on cutting down and turning out the clot, it was surprising to find that there were three separate spurting vessels in the tissue which had not been cut with the knife. They had probably been plugged, and for some reason had been opened afresh, and given rise to this very marked hæmorrhage.

I think the case in which the penis was so enormously swollen, interesting from that fact, and also from the fact that so much skin from the penis was lost. The patient certainly did remarkably well.

DR. F. S. WATSON: The first case seems to me a very valuable contribution to bladder surgery. It is, so far as I know, a unique case, as Dr. Stone has pointed out, and illustrates the advantages of a keen surgical intuition. The only case that I can recollect, in which recourse was had to the same procedures, is one which Guyon publishes. That was in a case of tuberculosis, the disease being limited to the bladder, in which the bladder was curetted and touched with the Pacquelin cautery. That patient recovered from the tuberculosis, the bacilli disappearing after that had been done. He did it in a second case, in which the bacilli disappeared, but the patient continued to have cystitis. So far as I know, these are the only two cases in which this procedure has been done.

The second case, of tuberculosis, was interesting to me more especially in regard to one point which I have had my attention called to lately, and which I expressed Saturday night in reporting a case of tuberculosis. Two years ago that patient came to me with small swellings in both epididymes. These preceded the appearance of urinary symptoms by a short time. The question came up again a few days ago, in a case where there was a chronic swelling of the testicle without suppuration or urinary symptoms, as to the desirability of removing the testes in such cases. It seems to me a very important one. Certainly I never watched such suffering as that which the first patient underwent after developing tuberculous disease of the bladder and kidneys which had its origin in the cheesy masses in the epididymis. If anything could be done to relieve these cases I think it would be of the greatest possible importance. In my opinion these chronically inflamed testes should be removed as soon as possible. I would also like to call attention to the inefficacy of divulsion in the fourth or fifth case, and point out the fact that it would seem to have been a case well suited to the cutting operation with the Maisonneuve, using the small knife first, and later the larger one of Otis. It is in these cases that this operation is most appropriate and efficient.

DR. CHEEVER: I would not be willing to let so interesting a series of cases pass without adding a little to it from my own experience. In the first place, in regard to the permanent opening. My experience is very small; I have seen but one case. I did the operation upon a brother physician at his own request. He had been a patient of the late Dr. Curtis. He suffered very much from irritability of the bladder, and desired an outlet to be made. The operation was done but afforded no permanent relief, although the opening was not allowed to close for a good while. With regard to the tuberculosis, I believe that I have a case at the present moment, in which an indolent abscess has formed between the perineum and bulb, and side of the sacrum. At first it was thought to be a fistula, but later it was found to be not urinary, but a sinus, discharging small cheesy masses which came from the deep tissues about the nates and perineum. The patient was a young man of very feeble habit, and of a strongly tuberculous family.

In regard to operations for extravasations, I would like to say that I can recall no case which has failed to do well where I made a direct opening so as to give exit to the extravasated urine through the perineum except in a few cases where it was afterward found as shown at the autopsy, that disease of the kidney existed. I think that every one will agree that these cases are very appalling and threatening; that they often occur in very dissipated individuals; and frequently in consequence of a debauch or something of that sort, and the extravasation is very large and very destructive, and the patient appears to be reduced by them to a low ebb; that the relief by the direct outlet through the perineum is immediate and very great, and almost all cases recover unless there proves to have been some disease of the kidney. In that case I think cases almost all die.

The only other point is in regard to the fifth case. I have had in the course of a number of years two cases of great destruction of the penis. One case was rather unusual, in which the patient got drunk and lay out in the snow, with his genitals exposed. Frostbite of the genitals must be very rare, of course. In this case the penis froze, and subsequently sloughed, with great loss of tissue. In the other case the patient was about some machinery and incautiously straddled over a revolving arm, which caught his trousers and rolled him up rapidly, caught the scrotum, and stripped off pretty much all the skin from the penis. Both these cases survived. Both were patched up in various ways by plastic operations, and had resulting organs through which they could pass water, etc., pretty well. In both of them there were these

painful erections, which I first looked at as evils, but which on more mature consideration I came to regard as really beneficial to the individual, in spite of the suffering, for if they had not occurred the subsequent contractions would have been very much greater. They kept the organ more or less distended through a certain part of the twenty-four hours, and in spite of the patient's sufferings, I have no doubt they were beneficial in the subsequent history of the case, for the parts, especially about the urethra, were not bound down by adhesion.

DR. PORTER: I would like to make one more suggestion. It is a question, in the light of what Dr. Cheever has just said, whether some of these cases in which a free opening through the perineum has been made for cystitis — those cases that do not recover — would not be benefited by curetting the bladder. Whether it is not due to the fact that the mucous membrane is in such a flabby granulating condition that there is no chance for recovery. I only throw out the suggestion as a question to be considered in these operations, in reference to making a much more careful exploration of the bladder with the finger to determine that, in cases that may present themselves hereafter.

DR. J. C. WARREN: In the after-treatment of cases of perineal section, I have of late been in the habit of introducing the catheter through the perineum, and not through the penis. I was led to that custom by an experience of mine in one case, where the catheter had been retained for a couple of days, the wound was healing nicely in the perineum, and had covered over the catheter, when a gush of urine took place outside the catheter, and an extensive extravasation into the scrotum was the result, with sloughing of the scrotum. It always seems to me, best therefore, to drain the bladder just as you would drain an abscess cavity with a drainage-tube, until a period has arrived when such a disaster as that spoken of would have been impossible; that is, when a fistulous opening had been made through the perineum, surrounded by granulations. After that, this fistulous opening might be allowed to contract, just as the fistulous opening in the trachea would close in after the removal of the canula, and the urethra can be kept open by sounds. That is a very convenient way of draining the bladder, also, because the English rubber catheter can be kept between the patient's legs, and can emerge through an antiseptic dressing. I have had no bad results from that mode of treatment.

DR. M. H. RICHARDSON reported a

CASE OF SUPRA-PUBIC CYSTOTOMY FOR TUMOR IN THE BLADDER.

and DR. F. S. WATSON followed with a

CASE OF PEDUNCULATED PAPILLOMA OF THE BLADDER, SUCCESSFULLY REMOVED BY PERINEAL OPERATION;[3]

and showed

A NEW FORM OF PERINEAL DRAINAGE-TUBE.

DR. RICHARDSON: Of course it is impossible to come to any conclusion in one case, but I have felt ever since this operation that if we had done the perineal operation this patient would perhaps have gotten well. In going over the operation in my mind since, there is nothing that I would have done differently in doing it a second time, unless it were the providing for drainage through the outer wound. The bladder was sewn up, leaving a small opening, then the wound was sewn together in the upper part, leaving sufficient space, as it seemed, for the drainage of the bladder, so that, in case of extravasation of urine outside the tube, which I don't see how you can prevent, it would not be forced down in the cellular tissue outside the bladder. I have not in mind the statistics of recovery after cystotomy, but my impression is that they are very favorable indeed; that some men have done a very large number of supra-pubic operations for stone without a death. Dr. Watson has put it exactly as it seems to me. The operation to be selected would vary according to the position of the tumor. If it is easily in reach of the finger, then the perineal operation would be sufficient. I do not see any way in which you are going to avoid the risk of extravasation of urine into the cellular tissue around the bladder.

DR. WATSON: The way in which the Frenchmen overcome that difficulty, and they have been very successful in doing so, is in the enjoyment of a double drainage-tube. The wounds are left opened, then whatever urine is extravasated beside the tube is not forced into the tissues under pressure, but runs out over the wound without harm resulting. Guyon's cases show that very decidedly. The Germans almost always sew up the bladder wound, on the contrary.

I was very much impressed with the fact when last summer I did supra-pubic cystotomy for tumor of the bladder, that it was not good surgery to sew the bladder wound tight where there was much bleeding in the bladder unless there is a very large opening in the perineum, for the pain from tenesmus was very severe and the strain on the suture was great. I do not think that any stitches would have stood the strain.

DR. ABNER POST showed a

CALCULUS FORMED ABOUT A PIECE OF CATHETER.

DR. MIXTER showed a

MODIFIED UTERINE ECRASEUR

of his own invention, and Dr. C. B. Porter, who had used the instrument in a case of hysterectomy, spoke highly in its favor.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

STATED MEETING, June 12, 1888, C. B. NANCREDE, M.D., in the chair.

DR. JOHN S. MILLER read the following paper:

A CONTRIBUTION TO THE STUDY OF BONE REPAIR.

The recent observations of Macewen[1] have done much to stimulate the study of bone repair, and have thrown not a little light upon the function of the medullary cells in osteogenesis.

The resort to mechanical irritation of the medullary tissues as a means of accelerating bone repair, is an old procedure. Nancrede[2] claims a priority in this for America. As far back as 1793 Eve[3] relates that the lay surgeons of the frontier were wont to make multiple perforation of the external table of the skull where

[1] Annals of Surgery, vol. vi, p. 289 et seq., 389 et seq.
[2] Internat. Encycl. of Surg., by Ashhurst, vol. v, p. 8.
[3] Remarkable Cases of Surgery, p. 35. Philadelphia, 1857.

necrosis had followed the Indian mutilation of scalping. And twenty years ago Agnew [2] resorted to the same procedure in a case of injury to the head. A fatal termination of the case, however, by encephalic complication, rendered the experiment incomplete. Reports of success by this procedure have been recently multiplied to an extent which will excuse us from repeating them in detail.

That, furthermore, medullary proliferation is not only an element in osteogenesis, but is of itself sufficient to that end without peritoneal coöperation, is evidenced by the case of Macewen,[4] in which a considerable restoration of the humerus was secured "by bone-transplantation," after a suppurative inflammation had destroyed both the shaft and its periosteum. The date of this observation is 1878.

Whether the introduction of proliferating medullary cells into ordinary connective tissue granulations may convert the whole into osseous tissue, or that a few osteoblasts will, so to speak, leaven the whole mass, is a question involving grave doubt, but the affirmative would seem to receive some support from the case which Nancrede [5] relates in 1883. An extensive laceration had caused denudation and necrosis of the ulna in two-thirds of its extent. The process of repair had been delayed, he drilled numerous holes through the sequestrum into the medullary canal, and, to quote his own words, "in a few days granulations sprang up from the ulna and fused with the granulations of the soft parts, and, in course of time, the fragment was separated."

That the procedure in this case had the effect of stimulating osteogenesis from within, we can readily believe; but concerning the fusion with granulation tissues without, a more accurate observation than is recorded by Nancrede is desired. Although by analogy we might conceive it possible, inasmuch as repair within the bone is by ossification of an embryonic tissue derived from the connective tissue around the bloodvessels of the medullary spaces. A similar case is reported by Macewen,[6] in which granulations appeared upon a surface of bone completely denuded of its periosteum, and gradually spread until they became united with the granulation tissue at the periphery of the wound. Macewen, however, infers from this observation that:

"The periosteum covering a bone may be completely destroyed or permanently removed, yet the denuded bone may not only retain its vitality, but may throw out cells which will cover it and form a new periosteum."

These cases would seem to confirm Macewen's dictum that the periosteum has no part whatever in the regeneration of bone. But the first case I shall present to your notice this evening demands a different hypothesis for its explanation.

The patient, D. M., aged fourteen years, suffered from an osteomyelitis of the right tibia, resulting in total necrosis of its diaphysis. A complete involucrum had formed around the sequestrum and afforded an unsteady support to the body weight. It was covered with the thickened periosteum. A number of fragments had been removed from time to time, and the parents had refused to entertain for him the proposal of amputation. The case, however, when it came into my hands, had become from septic infection so desperate that I was compelled to do something radical at once.

Exposing the shaft, or rather the involucrum, through its whole length, I made with trephine and saw a fenestrum large enough to permit the removal of the remaining sequestra, and cleared out the whole canal. Both epiphyses were found carious upon their exposed surfaces, and were scraped to the limit of safety. In a few days a superficial necrosis took place upon the inner surface of the tube.

Demarcation was, however, promptly effected by the free use of aluminum acetate [7]— that sheet-anchor in all sloughing wounds — and a fine layer of minute granulations became the field for any osteogenesis which we might hope to witness. During the long process of repair with the carious epiphysis as a never-failing source of bacterial supply, it was no trifling task to keep this extensive opening dry and sterilized. Furthermore, neither the patient, the household, nor the neighborhood could endure frequent dressings without great nervous prostration.

The requirements of the case were successfully met by a mixture of iodoform and starch, in proportions which varied with the changing conditions. The cavity of the wound was filled with this dry powder, and to the whole was applied a closed dressing of gutta-percha tissue. The purpose of the starch was to absorb the excess of moisture incident to a closed dressing as well as to dilute the iodoform. As soon as the powder became saturated it was removed by a stream of sterilized water, and the wound was filled and closed as before. The periods of dressing were gradually increased from three to ten days. I mention these details, because without them, or similar ones, we can wait in vain for the desired repair. In process of time the hollow of the involucrum became completely filled with granulation tissue, which continued to extend until it fused with the granulations from the soft parts, and finally the whole became covered with a new epithelium which had gradually spread from the edges of the wound. The tissues became now denser, and offered more and more support to the body weight until, as you see, he has acquired a very useful limb, and can walk without discomfort.

We must, therefore, infer that a metamorphosis into bone has taken place, and as the original diaphysis was gone with its medullary structure, we can find no osteogenic agent in the result other than the periosteum.

We must draw a similar conclusion from the recent case reported by Ceci:

The patient, a young man, developed an acute osteomyelitis of the left scapula five days after circumcision for inflamed phimosis. One month later, Ceci [8] extirpated the bone, making the usual L-flap. The periosteum was left intact as far as possible, and the arm was preserved. The patient recovered rapidly, and there was a subsequent regeneration of the bone.

The only possible explanation of this result is by the hypothesis of periosteal agency or coöperation.

The second case which I present is in confirmation of Macewen's proposition that, "a portion of bone which has its continuity severed on all sides, and has had all its periosteum removed, is capable of living and growing.

[4] Loc cit., p. 301.
[5] Transactions of the Philadelphia Academy of Surgery, 1888.

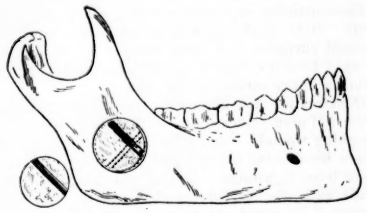
[8] Centralbl. f. Chirurgie, Dec. 17, 1887.

This is in contradiction to our inference in the case of the tibia, and can be reconciled only by the assumption that the discovered laws of osteogenesis are of a lower order, subject to some general law of which we are as yet ignorant. But to the case:



Mrs. L., aged forty-seven years, had suffered with a neuralgia of the maxillaris inferior, for the relief of which all medical means had been exhausted in vain, and which, therefore, left to my option only the *dernier ressort* of neurectomy. The mode of operating was the usual one. The ramus was trephined near the angle of the jaw, the canal was exposed, and about two inches of the nerve trunk were drawn out and exsected. The button was, however, returned after having been sterilized in a 1 to 1,000 solution of corrosive sublimate, but it was not returned to its old position. With a view of imposing a barrier to the reproduction of the nerve, it was so rotated around its vertical axis that the groove upon its lower surface stood at right angles to the axis of the canal. Not only did the wound close by first intention, but the button grew solidly in its position. Now, the curious thing in the case is, that before trephining I had carefully removed the periosteum, so that the latter can claim no part in the subsequent bone-repair. After seven months there has been no return of the disease.

DISCUSSION.

DR. JOHN B. ROBERTS: It is a curious fact that the medical mind has not appreciated the possibility of bone-production, despite the frequent instances that must always have come under notice. I was taught in cases of comminuted fracture to take out the spicules of bone that were entirely separated from the larger fragments, lest they should necrose and give rise to trouble. Now it is the practice of the best surgeons to leave the spicules, and we find that often they do not die, and that they assist in the process of union and solidification. This experience is in the same line as the facts given by Dr. Miller in connection with his interesting cases. If these spicules of bone can reunite, why not the button removed by trephining? Why is it not good practice to insert, when necessary, a portion of dog bone or chicken bone, as, indeed, has been done? We must not forget, however, the importance of asepsis, and that it is antiseptic surgery that has made these procedures possible.

In a case which Dr. Miller reports to-night, where he rotated the button of bone, turning the groove in which the inferior dental nerve had run at right angles to its former direction, I should be inclined to go still further and turn it upside down. The bottom of the pit in which it is to be placed, and the periosteal surface of the button being scraped, the ungrooved, freshened surface, formerly external, would then be placed inward, and a bony plug would be interposed between the divided ends of the nerve, probably preventing the reunion and return of pain which so often occur.

The case of tibial resection has been very interesting to me, as I have recently operated upon a similar one; the patient being, however, a woman of about fifty years, so that I cannot hope for as complete a closure of the cavity in the bone as in this growing child, exhibited by Dr. Miller. In that case I removed the whole front of the tibia, going as near the articular cartilages above and below as I dared. The process of repair is like that we see in a tree. We know that if a foreign body is inserted into a wound made in the trunk of a young tree the process of cell-growth will go on about it, and finally it will be completely covered in, and its presence be unsuspected, until, perhaps, the saw strikes it, as the tree is being converted into lumber.

Dr. Keen, in his recent case of trephining for brain tumor, returned the button of a skull removed, and the patient was able in a few days to walk around with a perfectly healed and reunited cranium. Then we know what the dentists do in the way of transplantation of teeth, or return of teeth to their original sockets after removal of diseased portions. More remarkable still is the implanting of old, dried teeth into new sockets, bored in jaws from which even the alveolar process had disappeared, and becoming fixed there.

DR. GEORGE E. STUBBS: In reflecting upon these cases and similar ones, it occurs to me that perhaps in the numerous resections we have done in army and in civil practice, we have made mistakes. Surgery has advanced immensely since the war-time, and antiseptic surgery has opened new possibilities. Often, in my army practice, we removed all the bone when there had been a comminution. I should now, with our new light, try to save more of the broken bone, and so shorten the period of recovery.

In regard to operative treatment of neuralgia, I believe that we are entering upon a stage of work that will be much enlarged in the near future. I had a case recently in which neuralgia of the interior dental nerve had existed for nearly seven years. I removed one and three-fourths inches of bone with the dental engine, took out as much of the nerve as I had access to, and dressed and treated the wound antiseptically. The wound healed by first intention, and as yet there has been no return of pain, so that I consider I have obtained a very good result.

The Chairman, DR. NANCREDE: The first question to be answered in a discussion of this kind is: what constitutes the periosteum? If we mean a fibrous membrane, the inner layer of which consists principally of yellow, elastic tissue, then we must agree with Macewen's extreme views, and admit that it has nothing to do with bone-repair. But, if we study the normal process of bone-development, I, at least, must arrive at a different conclusion. The long bones are laid down in cartilage, a temporary structure. How do they ossify? By means of this very periosteum, which Macewen treats with such contempt, and which Ollier exalted too highly. There is a third layer of the periosteum in direct contact with the bone, and this layer is composed entirely of those elements which, wherever we see them, we recognize as the agents of ossification — the osteoblasts. The temporary cartilage is invaded by connective tissue, ingrowths from the periosteum, covered with osteoblasts,

and is eaten up by them; and we find it permeated, and finally replaced by a network of fibrous tissue covered with osteoblasts. A certain number always remain beneath the periosteum. A certain number, very small, remain in the Haversian canals, a still larger number in the medulla.

It is clear to me why compact tissue dies; it has so few osteogenetic cells. The medullary tissue lives because it is comparatively rich in osteogenetic elements. Why does bone die when the periosteum is stripped off? because the resulting inflammation is so severe that the inflammatory tissue strangulated the osteoblasts in the Haversian canals. With antiseptic means we now control the inflammation, and the osteoblasts are not killed and the bone is saved.

We are very hard, nowadays, on the periosteum. The fibrous layer has nothing to do with bone-repair, but its osteoblastic layer is in direct communication through the lining of the Haversian canals with the medulla; it is practically one structure, and thus, if we look at this matter from the standpoint of a correct histology, we find that both views are correct, provided only that we have a distinct understanding what is meant by the word periosteum in each case.

As to Dr. Miller's cases, I cannot quite agree with him as to what formed the bone in the case of total excision of the diaphysis of the tibia. While the shaft was dying, new bone was formed by the deep layer of periosteum, but after that the medullary spaces of the involucrum completed the bone.

I would also take exception to Dr. Roberts's proposition to scrape the button of bone and turn it inside out in the case of trephining the jaw for neuralgia. By this process he would remove all the osteoblastic cells, and the compact tissue would have a very good chance of dying. One reason for failures in operations about the lower jaw is that it contains so little true medullary tissue, while, on the contrary, we can replace trephine buttons in the skull and have union, because the skull contains a large amount of such tissue.

I think Dr. Stubbs need not blame himself for his practice in resecting in military surgery. The necessary condition to bone-repair is that absence of suppuration afforded by antiseptic methods, and under the conditions present in the operation he speaks of he did right. And, to-day, he does right in trying to save the bone. In each case he takes the proper course in relation to the circumstances, and that is all that any one can do.

The case of Dr. Agnew, referred to in the paper, occurred some twenty odd years ago. I saw the operation. The wound was completely covered by granulations. The fact that a denuded external table did not always necrose was known to Potts and to all the older, as well as modern surgeons, and if Ollier had not led us astray by grafting, by insisting upon the periosteum being the sole osteogenetic agent, ignoring the fact that in removing it a layer of cells identical with those of the medulla are torn off, I think we would have arrived at a correct practice sooner. But surgeons went wrong by authority of Ollier, as they are now going wrong in the other direction by authority of Macewen.

In regard to the implantation of dead teeth, which Dr. Roberts refers to, the principle is probably the same as in the bony pegs we used to employ for ununited fractures. They are hollowed out by the granulation tissue which develops into a fibrous or even osseous tissue, and so holds the tooth in place by these newly formed digitations.

About twelve years ago I exhibited to this Society a case in which I resected four and a half inches of the humerus, and about two and a half inches were reproduced from the sawn end. This was without antisepsis. In the case referred to by Dr. Miller, where I drilled the ulna, I am sure that the bone granulations fused with those of the soft parts for these reasons: the shell of bone, when detached, was not more than one-fourth the thickness drilled through, while the new bone was nearly as thick as the ulna of the other side, as the cicatrix was not materially depressed. A recent experience in a case of knee-joint excision induces me to recommend that, instead of wiring fragments of bone, we nail them together, after having previously drilled, or not, according to circumstances, allowing the heads of the nails to project through the skin. We thus save trouble, and avoid damage in the removal.

Dr. Roberts: Dr. Nancrede misunderstood me in regard to scraping away the cancellated tissue in reversing the plug in the case of trephining the lower jaw. I would scrape only what he calls the fibrous periosteum from the button, and from the bottom of the pit in the jaw I would take away the cancellated structure sufficiently to remove all trace of the nerve canal. The two raw surfaces would be placed together, and, by the sinking of the button, would be a solid, bony plug, interposed between the nerve ends.

Dr. Miller: I do not see any advantage in reversing the plug over rotating it. The groove being at right angles to the course of the nerve, the part in contact with the nerve is still solid bone, and the groove does not matter at all. In relation to the tibia case, the reason I emphasize the fact that the repair took place from the periosteum is because there was entire death of the old bone with the involucrum, and the periosteum did not die.

Recent Literature.

Surgery: its Theory and Practice. By William Johnson Walsham, F.R.C.S., etc. 236 illustrations, 655 pages. Philadelphia: P. Blakiston, Son & Co. 1887.

The object of the writer of this little volume has been to furnish a work giving in as concise a manner as possible those facts which give to the student a general insight into the theory and practice of surgery, and which is not intended to take the place of the standard works and exhaustive treatises on this subject. For this purpose it is well written, and presents the subject in a manner which makes the volume a student's useful handbook. It is issued in a convenient form in clear type, is neatly bound, and contains many instructive illustrations. For a practitioner, the style is too concise, and the omission of many important details make it in many instances a mere compendium of fundamental principles and pathological or clinical facts.

— There has recently been presented to the Paris Anthropological Society a "Catalogue of Prehistoric Crania contained in the Broca Museum." It refers to 653 specimens representative of time from the earliest epoch to the Merovingian, inclusive.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 16, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

THE TOPOGRAPHY OF THE BRAIN.

IN the *Forum* for August, Professor Charcot, in reply to the article of Brown-Séquard in the April number, states a series of propositions, which he regards as summing up the existing knowledge of cerebral localizations, and gives weighty reasons therefor, based on anatomico-clinical facts.

In the endeavor to ascertain the function of definite portions of the cortex, Charcot sets aside, as of only secondary or subsidiary value, the results of experiments on animals, of which Ferrier has presented such a complete embodiment in his "Functions of the Brain." He emphasizes the differences which exist between the human cerebrum and that of animals. The brain attains in man a degree of development and perfection not reached in any other species. Its functions become complex, while at the same time its morphology undergoes important modifications. Now, as regards localization, morphological details are of the first importance. As for functions, even if we take account only of those common to men and animals, they are not performed in all in the same way. The higher an organism stands in the animal scale, the more strictly are the purely reflex functions subordinated to the functions of the higher centres. A decapitated frog performs with its legs coördinated automatic movements; not so a decapitated dog. In the dog, brain lesions, even of considerable extent, produce only incomplete paralysis, often passing away, while in man the like lesions cause incurable functional troubles. These examples are enough to show how much reserve is necessary in drawing inferences, as regards brain functions, from animals to man. The results of experimentation can give only presumptions more or less strong, but never absolute demonstration. Hence, the only really decisive data touching the cerebral physiology of man are those developed according to the principles of the anatomo-clinical method. This method consists in ever confronting the functional disorders observed during life with the lesions discovered and carefully located after death. This is the method that enabled Laënnec to throw light on the difficult subject of diagnosing pulmonary affections, and it has also materially helped the diagnosis of diseases of the liver, kidney, and spinal cord.

Taking, then, his stand on the rigorously ascertained data of the anatomo-clinical method, Charcot proceeds to formulate certain propositions which he thinks may now be regarded as established:

(1) When a brain lesion, whether cortical or of any other sort, is accompanied by motor paralysis, the seat of the paralysis is always on the side opposite to that of the lesion. This proposition is universally accepted by physicians, and in clinics it may be said to have the force of a law. Granting, Charcot says, that this law is subject to exceptions, these exceptions are so rare that, as far as clinical diagnosis is concerned, we may leave them out of account and hold it for a well-established truth that a paralysis of cerebral origin presupposes a lesion of the hemisphere of the opposite side. If, now, we turn to the study of disorders consequent on lesions of the cortex, we find that hemiplegia is often the consequence of these lesions. But not all lesions of the cortex are accompanied by hemiplegia; they are so only when certain conditions as to the extent of the lesion and its seat are present.

(2) Anatomo-clinical research shows that even considerable alterations in the gray matter of the brain cause no motor disturbance when they are localized in certain regions; for example, the sphenoidal, occipital, and inferior parietal lobes of the *pli courbe* and of the insula, the orbital lobule, and the anterior portion of the first, second, and third frontal convolutions. These portions of the brain may be destroyed by softening, may be compressed or irritated by tumors, by bony splinters, or by effusion of blood, without in the least affecting motility.

(3) The case is totally different if the region destroyed is that corresponding to the two ascending frontal and parietal convolutions and the adjoining *replis*, namely, the paracentral lobule, the foot of the first three frontal convolutions, and of the superior and inferior parietal lobules. In such cases we always find hemiplegia of the side opposite to that of the lesion. It is from such considerations as this that we formulate the existence of a well-defined motor zone in the cortex. This zone occupies pretty nearly the middle portion of the external surface of each hemisphere.

(4) The above conclusion is confirmed by anatomo-clinical observations of another order. It has been clearly proved that among the cerebral lesions *en foyer*, there are some, that is, those of the motor zone, which are sure to produce secondary degeneration of nerve-fibres proceeding from the cortex; descending sclerosis, in fact, regularly appears when the foyer comprises the two ascending convolutions (ascending parietal and ascending frontal) and the contiguous parts of the frontal and parietal lobes.

(5) The so-called motor zone in itself, shown by clinical facts — supported by the findings of the autopsy — to be resolvable into distinct centres, each

concerned with the movements of some special part of the body. There is, for instance, a monoplegia due to lesion of the cortex. In 1883, Charcot was led to conclude from researches made with Pitres that "the cortical motor centres for the two members of the opposite side are situate in the paracentral lobule and in the superior two-thirds of the ascending convolutions; that the centres for the movements of the lower part of the face are situate in the upper third of the ascending convolutions; that the centre for the isolated movements of the arm lies in the middle third of the ascending parietal convolution of the opposite side." Nothnagel reached the same conclusion through a close analysis of a multitude of facts, and these have been confirmed by observations published since 1883. Some recent facts, moreover, go to show "that the paracentral lobule with the uppermost part of the ascending frontal and parietal convolutions has especially to do with the motility of the femur and leg."

Charcot concludes his article by reference to the facts of what is called "Jacksonian epilepsy," and its relations to certain irritative lesions of the motor zone. He considers it as established that in the great majority of cases partial epilepsy results from lesions of the cortex, limited affections with quick and progressive evolution (neoplasm, superficial encephalitis, meningitis, whether acute or chronic). The lesions which produce it are usually on the motor zone itself, but they may lie outside of it, provided the affection is capable of irritating the elements of the motor convolutions. He alludes to the impregnability of Broca's doctrine of the speech centre in the left hemisphere, and regards it as sufficiently settled that the region of the cortex, lesion of which produces "word-deafness," is in the first frontal convolution. As to *agraphia* and *word-blindness*, we are not yet absolutely settled as to the seat of the lesion which produces them.

The propositions which he has stated, no longer, he says, meet with any serious contradiction among clinicians; the apparently contradictory facts brought forward by the few opponents will not bear methodical and rigorous criticism.

EFFECT OF ERGOT ON THE INVOLUTION OF THE UTERUS.

Some experiments have recently been made by Drs. Herman and O. C. Fowler, and reported to the Obstetrical Society of London, by which the authors sought to ascertain the effect of prolonged administration of ergot on the involution of the puerperal uterus.[1] To determine whether the medicine had any action or not, they gave an ergot mixture to one set of patients, fifty-eight in number, in repeated doses daily for a fortnight after labor. To another set, sixty-eight in number, only a single dose of ergot was given after labor, and no more. In both sets of patients they measured the height of the uterus above the pubes on successive days of the lying-in period. They found that in the cases treated by the continuous administration of ergot the uterus diminished in size more rapidly than in those in which one dose only was given. They compared the two sets of cases as to the duration of the lochial discharge, but on this they did not find that the ergot treatment produced any appreciable effect.

[1] Journal of Obstetrics, May, 1887.

At the same meeting Dr. Bloxall referred to two sets of cases occurring in his Lying-in Hospital, each having to do with one hundred patients. Every alternate patient admitted to the hospital was given a mixture three times a day containing fifteen minims of liquid extract of ergot. This was kept up during the first three days of the lying-in. The two series of observations were carried on simultaneously. In the second series the routine administration of the ergot was omitted. By contrasting the two series of cases, Dr. Bloxall concludes that the practice of giving ergot during the three days following delivery tends to prevent the formation of clots, and to hasten their expulsion, and to diminish the frequency, intensity and duration of after-pains. That if omitted at first, but given afterwards, the ergot mixture tends to promote the expulsion of the clots and relieve after-pains.

Dr. Dakin at the same meeting reported some observations which seemed contradictory to the conclusions at which Drs. Herman, Fowler and Bloxall had arrived, and claimed that the results of his studies went to show that the continuous use of ergot, by keeping up a tonic state of contraction instead of allowing normal alternate contraction and relaxation, would favor retention of clots, and hinder rather than help the normal process of involution.

THE YALE THERMOMETRIC BUREAU.

The Thermometric Bureau established in 1880 in connection with the Observatory of Yale University is accomplishing a work which physicians ought to appreciate. It has examined a gradually increasing number of thermometers during the years of its existence, but its usefulness is not measured by the number of instruments that pass through its hands. There is from year to year an improvement in the quality of instruments of American manufacture submitted for verification, both actual and relative to foreign manufactures, and the Observatory claims a share of the credit for this improvement.

"It may now be fairly said — as it could not have been said before the institution of this Bureau—that the best clinical thermometers of American manufacture compare favorably with the best foreign manufactures, both in the smallness of the amount of the required corrections and in their uniformity throughout the scale." Such was the statement of the managers of the Observatory in their last year's report, and this year they find occasion to say that their good work is still progressing.

MEDICAL NOTES.

— The *British Medical Journal* quotes from the *Archives de Médecine et de Pharmacie Militaire* for last year, an account of the seventeen patients who were killed or wounded by the explosion of a shell charged with the new explosive, melinite, in the arsenal at Belfort, in March, 1887. Only six recovered from their injuries, the remainder succumbing either to severe damage to the head, trunk, bones or blood-vessels, or to septic changes. The authorities believed that the explosion was due to chemical change in the compound with which the shell was charged. In the field during a campaign, freshly-laden shells would be expected to produce yet more violent effects. The patients mostly presented characteristic appearances. There were multiple, deep, very narrow wounds of the soft parts, caused by the entry of minute cubical fragments of shell, and in the depths of the wound the raw surface appeared as though tattoed with minute particles of foreign matter, as in gunpowder explosions. The injuries to bones were markedly localized, epiphyses being in some cases shattered without fissure of the shaft. The chief peculiarity was the presence of an intense yellow discoloration of the skin in every case, communicated to the patient's linen. The fragments extracted from the wounds appeared to be metallic splinters from the shell, no melinite nor any other chemical compound could be detected, nor did the patients who recovered exhibit any symptoms of the absorption of a chemical poison.

— The *Medical Press and Circular* quotes from a report of Dr. Keegan, Presidency Surgeon of Lahore, remarks showing some estimate of the immense boon conferred upon the women of India by Lady Dufferin's movement to supply them with medical aid in childbirth. The method of conducting labors throughout Central India only a year or two ago was as follows: The native midwives, or *dhaies*, on being called to a woman in labor, hasten delivery as much as they possible can by exerting pressure on the abdomen; they have no idea of waiting upon nature. The child being born, the mother is made to stand up, and pressure is again applied to the woman's abdomen, by means of the head or bent knee of the *dhaie*. A bandage is then passed round the woman's abdomen, and she is then allowed to lie down on a charpoy under which a charcoal fire is placed, which causes the room to become excessively warm. The room selected for the confinement is usually in the very interior of the house, and may be described almost as a hermetically sealed chamber. The day succeeding the birth of the child the mother is subjected to fumigation, which is continued for about twelve days, and at the same time indigenous stimulating condiments are given, which are supposed to give milk in abundance. These condiments are used four or six weeks. The mother is allowed to drink nothing but warm water for the first ten days. In the hot season of the year the charcoal fire is used both day and night for the first twelve days succeeding the birth of the child. Subsequently it is used from evening till early morning, and is not discontinued *in toto* until the expiration of a month or six weeks. During these six weeks the child is subjected to the same atmospheric conditions as the mother, and whenever it cries more fuel is added to the fire, and the child soon ceases to cry, owing to the effects of the carbonic acid gas. Dr. Keegan adds that this method of conducting confinements is, with some slight modifications, more or less prevalent throughout the greater portion of India.

NEW YORK.

— Dr. Henry Raphæl, of New York, died at Saratoga, August 4th, in the forty-eighth year of his age. He was born in Russia, but came with his parents to this country at an early age. After a public school education, he studied medicine and was graduated from Bellevue Hospital Medical College; subsequently serving as house-surgeon in Bellevue Hospital. Up to a few years ago, he had a large private practice, but failing health compelled him to relinquish it. Dr. Raphæl is well-known to the profession by his excellent translations of Vogel's "Diseases of Children" and Von Zeissel's "Syphilis," published by the Appletons. He also translated several works of German fiction, and for several years contributed largely to current medical literature.

— The coroner's jury in the case of Mrs. Levy, who was run over and killed by a 23d Street "bobtail" car finds that her death was directly due to the system of running such cars without conductors, and condemns the system as especially pernicious in a large and populous city. It then recommends the State Legislature to take such action as will require the New York horse-car companies to provide conductors as well as drivers for every car.

Miscellany.

THE USE OF COLD IN DIARRHŒAS OF CHILDREN DURING THE HOT WEATHER.

THE *Therapeutic Gazette* speaks thus, editorially, regarding the value of the treatment of summer diarrhœa in children by cold baths:

"As the heated term is upon us, we take the liberty of calling the attention of our readers to a practice concerning which we have frequently written, but which we do not think obtains upon the profession as largely as it ought to. Any one who watches the mortality-lists of our large cities knows that any marked ascent of the average heat-record of the thermometer is accompanied by a corresponding rise in the mortality-list; also that the rise is chiefly made up of infantile deaths, such deaths in turn being in great part the result of some form of diarrhœa. Whether these cases are called cholera infantum, or summer diarrhœa, or enteritis, or colitis, we believe that they are in great part the direct result of overheating of the body, and that they are to be best combatted by the use of the cold bath. In all such cases the physician should take the temperature of the little

patient, and if, as is generally the case, the bodily heat is distinctly above normal, systematic cold bathing should be enforced. It may be necessary to give the cold bath every two hours; it may only be required three times in the twenty-four hours. At first the child usually resists the bath violently, and the prejudices of the mother are often like the wall of a fortification; but, whenever we have persevered, the results have been so marked as not only to rapidly overcome the prejudice of the mother, but also to teach the child itself the value of the bath, and cause the outcries and resistance on its part to cease entirely. We wish that this treatment would be fairly tried by our readers, and reports made thereon through our columns."

ANTISEPSIS IN TYPHOID.

Intestinal antisepsia in typhoid fever cases seems to be in a good way of becoming of the highest importance, says the Paris correspondent of the *Philadelphia Medical Times* (July 16th). In the treatment of such patients, Professor Bouchard first introduced naphthol, and Dr. Legroux is at present applying it in his service at the children's hospital with great success. As soon as a child is brought in suffering with symptoms of typhoid, the intestines are at once cleaned out with calomel, given in doses of 0.30 to 0.60 centigrammes, depending on the child's age. The next day the intestinal antiseptic treatment is commenced as follows:

℞ Naphthol beta . . } āā 2 grammes, 50
Bismuth salicylate }

M. Divide in 10 powders, and give one every hour in a wafer, or mixed with a little milk or brandy.

If the diarrhœa is not important, the bismuth may may be left out and only the naphthol given, and if on the contrary there is constipation, then the following is used:

℞ Naphthol beta . . . . . 2 grammes, 50
Magnesia salicylate . . . . 2 grammes, 50 to 5 grms

M. Divide in 10 powders, and give one every hour until the bowels are free, and then continue with the naphthol only, as before.

It will be found that there will be a diminution or entire suppression of intestinal meteorism, and that the stools are disinfected, no longer giving the fetid smell of typhoid, and also the mouth and tongue will clear up, the general state will improve, the disease will evolute quietly, and the convalescence will be shortened under this treatment. Naphthaline was tried, but it was found so disagreeable to the patients — most of them refused to take it — that it had to be stopped. It also presents some danger of absorption.

STATISTICS AND TREATMENT OF PLACENTA PREVIA.

The *American Journal for Obstetrics* summarizes a paper by Nordman on the above subject from *Archives f. Gyn*, (XXXII., 1.) The aim of the paper is to solve the question as to whether the preferable method of treatment is by combined version and slow extraction. Forty-five cases occurring at the Dresden clinic, in a total of 5,779 labors, are utilized. Twelve cases were treated by tampon or colpeurynter, with or without rupture of the membranes, delivery being allowed to take place spontaneously, with a maternal mortality of 0 per cent, and an infantile of 16.6 per cent, excluding the cases where the fœtus was dead when first seen. In twenty-three cases, version was performed followed by immediate extraction, the maternal mortality being 17.3 per cent, and the infantile 5.8 per cent, excluding cases where the fœtal heart was never heard. In six cases, version and slow extraction was the method of treatment, one mother dying of sepsis and all the children being delivered dead. Although these data decidedly speak in favor of the first methed of treatment, it should be noted that, in all the cases so treated, there was marginal insertion of the placenta, which does not expose the mother to the same risk as the total insertion. By the second method the greatest number of children were saved. Nordman concludes that this method is preferable in hospital practice, whilst in private practice version and slow extraction should be the rule, notwithstanding the excessive infantile mortality. In case of placenta previa marginalis, the tampon will answer well both from the standpoint of the mother and of the child.

EVE ON ACTINOMYCOSIS.

Mr. Frederic Eve gives some interesting examples of cases of actinomycosis in the *Practitioner*, May, 1888. This disease belongs to the large group known to pathologists as the infective granulomata, the infective element being a peculiar vegetable fungus, the growth and distribution of which are associated with tumors formed of granulation-tissue. The fungus gains access to the body by means of a lesion of some mucous membrane or of the skin. A primary tumor is thus established, from which general dissemination may take place by means of the blood and lymphatic vessels. Clinically, this disease in man presents itself under somewhat varying aspects. When attacking the maxillary region, it generally commences with pain in one or more teeth; a swelling soon appears, and, after the lapse of weeks or months, the disease culminates in a diffuse general enlargement of one side of the neck or face. The swelling becomes soft and fluctuating, but, on opening the softened areas, only a few drops of pus escaped, and the tissues are found infiltrated with a soft, spongy granulation-tissue. The progress of the malady is extremely chronic, as a rule. In actinomycosis of the lung and thorax, pain in the side, with pleurisy or pleuro-pneumonia, are commonly the first symptoms. The duration of the disease in fatal cases varies from ten weeks to a year and a half or more. Secondary formations have been found in the liver, lung, kidney, spleen, intestines, brain, ovary, heart-muscle, and in the muscles and skin. Up to 1886, an analysis of seventy-five recorded cases was drawn up by Moosbrugger. In twenty-nine the disease was in the neighborhood of the lower jaw, in the mouth and neck; in nine in the upper jaw and cheek; in one case in the tongue, and in two involving the pharynx and œsophagus; eleven in the intestines and abdominal viscera; fourteen in the bronchial tubes or lung. In seven the seat of the disease could not be ascertained. As to the prognosis of this disease, there is little chance in man of a spontaneous cure, as sometimes happens in cattle similarly affected; operative measures are successful if the affected part be completely removed, and the patient may be free from a return for years; cases of visceral actinomycosis are necessarily fatal. In cases beyond the reach of opera-

tive measures, it has been recommended to inject a solution of perchloride of mercury; but unless the disease can be eradicated by the knife in its earliest stage, there is little hope of a cure. — *London Medical Recorder*, June 20, 1888.

FOREIGN BODIES IN THE RECTUM.

MR. D. H. GOODSALL, Assistant Surgeon to St. Mark's Hospital, has published "The Notes of Twenty Cases of Foreign Bodies in the Rectum," in the twenty-third volume of the *St. Bartholomew's Hospital Reports*, recently issued. From a consideration of these notes, the *British Medical Journal* gives the author's conclusions as follows: (1) That this form of accident is more commonly met with after thirty-five years of age, the average age in the twenty cases being upwards of forty-two years. (2) That a bone takes from one to nine days to pass from the mouth to the rectum. (3) That the pain in the rectum comes on suddenly while the motion is being passed. (4) That there is constant pain and discomfort in the rectum, and sometimes also in the adjacent parts, from the time of puncture until the foreign body has been removed. (5) That the site of the puncture is within the last inch or three-quarters of an inch of the rectum. (6) That when an abscess follows the puncture it begins to form within two or three days of the puncture. That when the case is seen early and the bone promptly removed, no ill effects follow the puncture. (8) That when a fistula has formed, the patient may, unless the internal opening is large, be cured by making only a free external opening. (9) That when it is necessary to lay open the fistula the wound made (the foreign body having been removed), heals much more rapidly than the wound does in non-traumatic cases of fistula. The cause of fistula is very important in cases of candidates for life-insurance, for if the fistula be of traumatic origin, no increase should be made in the rate of premium because of such a fistula. An ischio-rectal abscess, caused by a foreign body, should be opened as soon as possible. When the case is seen soon after the foreign body has punctured the rectum and before abscess has formed, the patient should be put under chloroform and the sphincter forcibly stretched. The foreign body should then be removed, either from the rectum or by an external incision. Then about two drachms of unguentum cetacei should be introduced into the rectum. The bowels must be kept confined for three or four days and then relieved by olive oil, not by aperients.

DEUTSCH-MEDICINISCHE-SCHRIFT-SUCHT; OR, THE GERMAN MEDICAL-JOURNAL HABIT.

DR. JOHN S. HAWLEY closed an address on the above subject before the Hospital Graduates Club with the following "song," which we copy from the *Medical Analectic:*

If we write so that nouns with their verbs don't agree,
That 's German, you know, quite German, you know.
If our meaning obscure and involved seems to be,
It 's German, not English, you know.
But that kind of writing you read in Berlin,
In Heidelberg, Wien, where we 've frequently been,
Don't mind how you end, if you only begin, —
Is German, quite German, you know.

O the queer things we do, and the queer things we see
Are German, you know, all German, you know.
No man in this wide world a surgeon can be
Till he 's German, all German, you know.

We spend all our money to emulate Koch,
He 's German you know, born a German, you know.
We cultivate germs tho' our raiment we "hock"
With our uncle, who 's German, you know.
We bully our confrères with Volkmann and Braun,
With Virchow and Schroeder their arguments down,
And we knock them all out with Esmarch's renown,
They 're Germans, native Germans, you know.
O the queer names we hear, and the queer names we quote,
Are German, you know, all German, you know,
We speak them, tho' each gives us a pain in the throat,
For they're German, true German, you know.

We take out the stomach and resect the gut,
That 's German, you know, quite German, you know.
The leaves of the journals in public we cut,
When they 're German, true German, you know.
Our talk has a bacteriological drift,
We pay "twenty marks" for a pipe, for a gift,
And we quote from the *Berliner klin. Wochenschrift*,
Which is published in German, you know.
O the marvelous statements that come from afar,
Are German, you know, all German, you know,
But of course it 's all right if it 's German — *nicht wahr?*
That 's the German for "aint it?" you know.

We think it improper to poultice a boil,
No German you know, would do so, you know,
And we make salad dressing with carbolized oil,
That 's the custom with Germans, you know.
With carbolic inhalers we muzzle our jaws,
We wear underclothes of iodoform gauze,
We ignore the effect, and talk big about cause,
Which the Germans do always, you know.
O the queer things we do and the queer ways we live,
Are German, you know, all German, you know,
Of squaring the circle the method we 'll give,
Or some German will give it, you know.

We consider a coccus the cause of a gleet,
That 's German, you know, quite German you know,
We dress a cut finger in a haystack of peat,
That 's German, true German, you know.
We put in a gum larynx and a celluloid tongue,
We exsect the spleen, and we resect the lung,
We save at the spigot, and leak at the bung,—
O we 're German, we 're German, you know.
But the queer way we feel when we count up the slain,
Is not German, you know, no, not German, you know.
And we 've not enough nerve yet, to exsect the brain,
As the Germans will soon do, you know.

We write in the journals a great deal of rot,
As do Germans you know, tho' they 're Germans, you know,
And we seek a small pin in a ten-acre lot,
For the Germans can find one, you know.
We discard the choice meat and chew on the bone,
We refuse the good bread and grasp at a stone,
We hoard oyster shells and the pearls leave alone,
That 's German, true German, you know.
O the queer things we do, and the queer things we write,
Are German, you know, all German, you know.
We will swear that the ace of the spade suit is white,
If some German but says so, you know.

On sterilized pap our young infants we feed,
That 's German, you know, quite German, you know,
And we hope by such means to improve on the breed,
For the Germans advise it, you know.
In training a puppy, or raising a foal,
In the search for an office, or the seat of the soul,
Or how to fit a square stick to a circular hole,
We get points from the Germans, you know.
O the queer tricks we play with our young babies' milk,
Are German, you know, all German, you know,
Of sow's ears we make purses of superfine silk,
By a process that 's German, you know.

We pour down the beer as tho' filling a tank,
That 's German, you know, true German, you know.
And we eat Sweitzer Kase and Limburger rank,
That 's German cheese with the gangrene, you know.
Frankfurters we love, and sauer kraut, too,
And we make no mistake when the spring Bock we brew,
But we bite off more science than we ever can chew,
When we follow the Germans, you know.
O for the queer things we eat, and the good things we drink,
Thank the Germans, you know, bless the Germans you know,
But we ball up our science, and our good sense we kink,
When we try German methods, you know.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 4, 1888.

Deaths reported 3,514: under five years of age 1,524; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,151, consumption 308, acute lung diseases 152, diarrhœal diseases 779, typhoid fever 97, diphtheria and croup 87, whooping-cough 67, malarial fever 33, scarlet fever 32, measles 28, cerebro-spinal meningitis 12, puerperal fever seven, small-pox five, erysipelas four. From whooping-cough, New York 19, Washington 10, Philadelphia nine, Brooklyn seven, Chicago six, Cincinnati and Pittsburgh four each, Boston and New Orleans two each, Baltimore, Haverhill, Newton and Fitchburg one each. From malarial fevers New Orleans 11, New York and Baltimore six each, Brooklyn and Washington four each, Philadelphia two. From scarlet fever New York 22, Brooklyn six, Pittsburgh three, Philadelphia one. From measles New York 17, Chicago five, Brooklyn and Baltimore two each, Pittsburgh and Worcester one each. From cerebro-spinal meningitis, Chicago four, Worcester three, New York and Washington two each, Nashville one. From puerperal fever Chicago four, New York two, Baltimore one. From small-pox, Philadelphia five. From erysipelas, New York, Brooklyn, Chicago, and Pittsburgh one each.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending July 21st, the death-rate was 16.0. Deaths reported 2,884: infants under one year of age 777; acute diseases of the respiratory organs (London) 166, diarrhœa 105, whooping-cough 68, measles 50, scarlet fever 31, fevers 27, diphtheria 23, small-pox (Sheffield two, London, Bristol, Preston, and Hull one each) six.

The death-rates ranged from 12.2 in Brighton to 21.1 in Manchester: Birmingham 16.1; Blackburn 13.2; Bradford 16.1; Leeds 18.9; Leicester 14.9; Liverpool 15.3; London 15.8; Nottingham 12.7; Sheffield 15.9; Sunderland 14.2.

In Edinburgh 16.3; Glasgow 23.1; Dublin 19.4.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS. — Programme of the Second Annual Meeting of the AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS, to be held at Washington, D. C., September 18, 19, and 20, 1888.

Officers for 1888. President, Dr. Edward L. Keyes, of New York. Vice-President, Dr. George Chismore, of San Francisco, Cal. Secretary, Dr. Robert W. Taylor, of New York. Members of the Council, Dr. John H. Brinton, of Philadelphia, Pa., and Dr. Francis B. Greenough, of Boston, Mass., together with the officers of the Association.

First Day. Tuesday, September 18th. — Business Meeting at 9 A. M. Morning Session at 10 A. M. Address of Welcome, by the President, Dr. Edward L. Keyes. Pyæmia as a Direct Sequel of Gonorrhœa, by Dr. Roswell Park, of Buffalo, N. Y. Clinical Observations on Gonorrhœa, with Special Reference to Etiology, Duration and Treatment, by Drs. John P. Bryson and Edwin C. Burnett, of St. Louis, Mo. Retrojections in Gonorrhœa, by Dr. Edward R. Palmer, of Louisville, Ky. Local Treatment of Chronic Urethral Discharges, by Dr. Frederick R. Sturgis, of New York. On the Relation of the Prostate to Chronic Urethral Discharges, by Dr. J. William White, of Philadelphia, Pa. The Diagnosis and Treatment of Chronic Urethritis, with Demonstrations of Instruments, by Dr. Oberländer of Dresden, Germany. To be read by Dr. John A. Fordyce, (by invitation). Adjournment at 1.30 P. M. Afternoon session at 3 P. M. Connection between Masturbation and Stricture of the Urethra, by Dr. Samuel W. Gross, of Philadelphia, Pa. The Curability of Urethral Stricture by Electricity: An Investigation, by Dr. Edward L. Keyes, of New York. On the Radical Cure of Stricture of the Urethra by Dilating Urethrotomy, by Dr. Fessenden N. Otis, of New York. The Prognosis of Stricture Based on Thirty Years' Death Record at the London Hospital and the Practice at St. Peter's Hospital, by E. Hurry Fenwick, F.R.C S., of London, England. (By invitation.) Some Points on the Etiology of Stricture of the Urethra, by Dr. Robert W. Taylor, of New York. Adjournment at 6 P. M.

Second Day. Wednesday, September 19th. — Business Meeting at 9 A. M. The Operative Treatment of Hypertrophy of the Prostate, with Stereopticon Demonstrations of Specimens, etc., by Dr. Francis S. Watson, of Boston, Mass. Prostatotomy for Enlarged Prostate at the Age of Forty-Two Years, by Dr. Abner Post, of Boston, Mass. The History of the Filaria Sanguinis Hominis: Its Discovery in the United States, and Especially the Relationship of the Parasite to Chylocele of the Tunica Vaginalis Testis, Dr. William M. Mastin, of Mobile, Ala. Clinical Observations on Diseases of the Testicle, by Dr. L. Bolton Bangs, of New York. Case of Removal of Both Testicles for Recurrent Carcinoma, by Dr. Frank W. Rockwell, of Brooklyn, N. Y. Adjournment at 1.30 P. M. Afternoon session at 3 P. M. Some Points in the Differential Diagnosis of Bladder and Kidney Affections, with Demonstrations of the Cystoscope and Other Instruments, by Dr. Alexander W. Stein, of New York. Demonstration of a Perfected Evacuator and an Improvement in the Method of Removal of Débris from the Bladder, by Dr. Fessenden N. Otis, of New York. Stone in the Bladder in Connection with Splenic Leuchæmia, by Charles Williams, F.R.C.S., of Norwich, Eng. (By invitation.) Lithol-apaxy in Male Children, by Surgeon-Major Keegan, of Indore, Central India. (By invitation.) Case of Perineal Section for Traumatic Retention — Unusual Condition of the Bladder, by Dr. J. E. Michael, of Baltimore, Md. Adjournment at 6 P. M.

Third Day. Thursday, September 20th. Business Meeting at 9 A. M. Operations on the Kidney, by Dr. William H. Hingston, of Montreal, Canada. On the Effects of Rapid Changes of Altitude in an Advanced Case of Interstitial Nephritis, by Dr. George Chismore, of San Francisco, Cal. Case of Nephro-Lithiasis, Complicated with Hydro-Nephrosis, in which Lumbar Nephrotomy was Performed, by Dr. Frank W. Rockwell, of Brooklyn, N. Y. Malignant Tumors of the Seminal Vesicles; Two Cases with Specimens, by Dr. John B. Bryson, of St. Louis, Mo. Adjournment at 1.30 P. M. Afternoon session at 3 P. M. Case of Bowel Ending in the Urethra of a Child Four Weeks Old — Relief by Operation, by Dr. Arthur T. Cabot, of Boston, Mass. Unusual Case of Urethral Calculus, by Dr. Harvey G. Mudd, of St. Louis, Mo. The Congenital Anomalies of the External Urethral Orifice, by Dr. B. Kaufmann, of Zürich, Switzerland. (By invitation.) The Prophylaxis of Syphilis, by Dr. Prince A. Morrow, of New York. Syphiloma of the Vulva, by Dr. J. Nevins Hyde, of Chicago, Ill. The Value of the Tolerance of the Iodides as a Diagnostic of Syphilis, by Dr. J. William White, of Philadelphia, Pa. And papers by Dr. Félix Guyon, of Paris, France, Dr. Freund, of Strasburg, Germany, and others. Retirement of Old and Induction of Newly Elected Officers. Adjournment at 6 P. M.

THE VALUE OF CORROSIVE SUBLIMATE AS A PRACTICAL DISINFECTANT.[1]

BY WILLIAM B. HILLS, M.D., OF CAMBRIDGE.

IT is only within a comparatively few years that the exact nature of infectious material has been determined with any approach to certainty. Previous to this time, our knowledge of the relative value of disinfectants was necessarily very inexact, and their mode of action, although the occasion for numerous theories, entirely unknown. It was assumed, however, that infection had its origin in putrefactive processes. Any substance, therefore, which arrested such processes, or destroyed their chemical products, was considered to possess more or less value as a disinfectant. The only known test of the efficiency of these was their power to arrest decomposition, and this was determined by the presence or absence of odor.

Investigations of recent years, however, have proved as exclusively, perhaps, as is possible that certain infectious diseases are caused by micro-organisms. Consequently, all processes of disinfection are now based on the view that all such diseases are caused by micro-organisms, or by poisons which are produced by the vitality of such micro-organisms. In the present state of our knowledge, therefore, we consider as disinfectants those substances only which have the power of destroying the vitality of micro-organisms.

When the various substances formerly employed as disinfectants were measured by this test, it was found that nearly all of them are much less valuable than was formerly supposed; while some, including ferrous sulphate and the salts of zinc, which had for some years been considered of inestimable value, are absolutely worthless. The hypochlorites, which have always occupied a prominent place in the list of disinfectants because of their power to destroy organic matter and the chemical products of putrefaction, were found to be in fact very efficient; though it is probable that, as they had been hitherto employed, they were more often inefficient than otherwise, owing to a lack of any definite knowledge regarding the proper amount to be employed. With this exception, however, the only metallic salt found to have distinct value for practical disinfection was corrosive sublimate. This salt had been recognized for many years as an efficient antiseptic, and had also been included in the list of supposed disinfectants; but it had not been shown, by the tests employed previous to 1880 or thereabout, to have a superiority over other metallic salts of its class, sufficient to compensate for its expense and poisonous properties.

Our knowledge regarding the relative value of disinfectants as measured by their power to destroy micro-organisms dates from the researches of Robert Koch, published in 1881. Koch found that most micro-organisms are destroyed by a solution of corrosive sublimate of the strength of 1:5000; while a solution of the strength of 1:1000 is fatal to all. He also found that corrosive sublimate has a decided superiority over all other substances as an antiseptic. A solution of the strength of 1:1000000 had a marked restraining power on the germination of the spores of the *B. anthracis*, for example, while a solution of the strength of of 1:300000 prevented their development. The results of other investigators, while showing that its antiseptic and disinfecting powers are possibly not quite so great as claimed for it by Koch, still confirm the latter so far as to show that they are considerably greater than those of any other known substance, with the possible exception of one or two other salts of mercury, which for one reason or another are not so available.

As a result of these investigations, and more directly following the recommendations of the Committee on Disinfectants of the American Public Health Association, published in 1885, corrosive sublimate has taken the place, to a large extent, of all other disinfectants, for nearly every purpose excepting aërial disinfection. Every State Board of Health, to whose reports, for the past four or five years, I have been able to obtain access, has published the recommendations of this committee, thus giving them a wide circulation, and nearly every one has distinctly endorsed them as representing the best methods of disinfection known to us. The Board of Health of Maine alone objects to corrosive sublimate, on account of its poisonous properties, and because it forms an insoluble compound with albumen. Figures showing the exact extent to which it is used, can be obtained, if at all, only through local Boards of Health, and the reports of these are not easily accessible. There were used, however, in the city of Boston, according to the reports of the Board of Health, in 1884, 850 pounds; in 1885, 1,550 pounds; in 1886, 1,400 pounds; and in 1887, 2,250 pounds of corrosive sublimate for purposes of disinfection.

The value of corrosive sublimate, as measured by its power to destroy micro-organisms in aqueous solutions, is not denied. But the efficiency of a disinfectant, and the amount required for certain disinfection, vary with the nature of the material to be disinfected. The disinfecting power of corrosive sublimate for instance, is greater in an aqueous solution than it is in an albuminous solution; for in the latter case a part or the whole of the disinfectant unites with the albumen, forming a compound which has little or no disinfecting power. Thus Klein [2] found that one and the same kind of blood bacillus was completely killed by an aqueous solution of corrosive sublimate of the strength of 1:25000, whereas it remained unaffected by a solution in nutrient gelatine of the strength of 1:20000 of fluid, — or even by a solution in broth of the strength of 1:10000. In all processes of disinfection with chemical disinfectants, we should therefore take into consideration the chemical changes which the disinfectant undergoes when it is added to the material to be disinfected. If we act upon germs in the presence of material which is capable of forming, with the disinfectant employed, inert compounds, it is clear that the germs are likely to escape unharmed, unless we add such a quantity of the disinfectant that it shall be in sufficient excess after the chemical change is complete. Even then we do not attain perfect disinfection, if the inert compounds are such as are able to protect the germs in any way from the action of such excess. This is the case when we employ corrosive sublimate, or any other substance which coagulates albumen, for the disinfection of albuminous material. Under these conditions a coagulum is formed, and germs included within such solid masses may escape

[1] Read before the Massachusetts Medical Society, June 13, 1888, and recommended for publication by the Society.

[2] Report of the Local Government Board, London, 1885-6, page 155.

destruction and develop later when the material is thrown into the vault or other similar receptacle; for the excess, if any, is in turn converted to inert compounds by the albuminous material, ammonia, sulphuretted hydrogen or other substances with which it there comes in contact, or it is so far diluted as to become inefficient.

Considering corrosive sublimate in connection with these facts, we see no reason for denying that it is an efficient practical disinfectant for certain of the purposes for which it is recommended by the committee on disinfectants, and employed in this and other countries; bearing carefully in mind, however, that its use is for obvious reasons unjustifiable unless we can dispose of it in some other manner than through lead pipes. But for the disinfection of the excreta, vomited matters, sputum, etc., of persons sick with diseases known or suspected to be infectious, or for the disinfection of clothing or bed-linen soiled with such material, it is wholly unreliable, and is so recognized by sanitarians abroad. Yet a solution of the strength of 1:500 is recommended for these purposes by the committee on disinfectants, and following them, by most of the Boards of Health in this country.

An examination of the report of this Committee fails, however, to bring to light the slightest particle of evidence upon which such a recommendation could have been based. The statements made relative to corrosive sublimate are very contradictory and confusing; the biological tests recorded are few in number and very unsatisfactory; and the report, as a whole, shows evidence of hasty preparation, and is not at all creditable to the Committee. A brief review of the alleged evidence presented by this Committee in favor of corrosive sublimate will, I think, prove the correctness of this criticism.

It is to be observed, first, that the Committee recognize the fact that the quantity of disinfectant required for perfect disinfection depends upon the nature of the material in which the germs are contained — provided, however, the disinfectant is an oxidizing disinfectant. On page 19 of the report the apparently contradictory results obtained in two series of experiments with potassium permanganate are thus explained: "The wide difference as to the quantity of the disinfecting agent required in two series of experiments depends upon an essential difference in the nature of the fluid in which the germs to be destroyed were contained. The large amount of organic material present in the blood, as compared with that in the culture fluid used in the second series of experiments, fully accounts for the difference, for the disinfecting agent is, itself, destroyed by contact with organic matter."

Also, on page 14, we find the following: "The fact that the oxidizing disinfectants are destroyed in the reaction to which their disinfecting power is due, makes it necessary to use them in excess of the amount of organic material to be destroyed; otherwise germs included in masses of material not acted upon would be left intact in a fluid which is no longer of any value for their destruction, and, as a few germs may be as potent for mischief as a large number, there would be a complete failure to accomplish the object in view." The Committee make essentially the same statement on page 117, and thus conclude: "The only safe rule in the practical use of oxidizing disinfectants is to *use such a quantity of the disinfecting agent that it shall be in excess after the reaction has taken place.*" But, if it is necessary to take into consideration the chemical changes which take place in the use of oxidizing disinfectants, why is not the same precaution necessary in the use of all disinfectants? For there is scarcely a substance which has been suggested as a disinfectant which may not undergo some chemical change when brought into contact with such organic mixtures as require disinfection, and there is none which is more liable to change than corrosive sublimate. The Committee, however, either ignorant of this fact, or forgetting it in their haste, actually use the oxidizing property of the hypochlorites, which makes them the most valuable chemical disinfectants at our disposal (since, if we use an excess, we destroy organic matter and germs at the same time), as an argument against them and in favor of corrosive sublimate, which not only may undergo more changes than do the hypochlorites, but such changes as may render it absolutely worthless.

"For this reason," they say (page 14), "the metallic salts, such as corrosive sublimate, which are not destroyed by contact with organic matter have a superior value for the disinfection of masses of material left *in situ*, such as the contents of privy-vaults and cess-pools. In this case, even if germs enclosed in an envelope of albuminate of mercury escape destruction, they will be prevented from doing mischief so long as they are included in such an envelope, and the wonderful antiseptic power of the reagent used will prevent their development for a sufficient length of time to ensure the complete loss of vitality of any pathogenic organisms present." It is, however, a well-known chemical fact that corrosive sublimate *is* destroyed, or, at least, undergoes chemical changes when brought into contact with organic matter. It is immediately converted by albumen to the insoluble albuminate of mercury. For this reason, albumen is recognized as the most efficient antidote in cases of poisoning by corrosive sublimate. Corrosive sublimate in solution is further decomposed by a very large number of other compounds, organic and inorganic, and by unknown constituents of most organic mixtures. There are but few substances whose range of incompatibilities is so wide. The Committee apparently admit the possibility of its uniting with albumen, but think we shall, even then, attain perfect disinfection, because the germs will be imprisoned within the envelope of albuminate of mercury, and will *probably* be prevented from developing. But this is not disinfection. Disinfection consists in the *destruction* of disease germs.

Later, the Committee realize their error, and admit the inefficiency of corrosive sublimate for the disinfection of excreta. Sternberg thus writes (page 59), referring to some experiments which show that this substance is not efficient for the disinfection of fresh tuberculous sputum: "The experiments of Schill and Fischer, which I had not read when the recommendation was made (referring to the use of corrosive sublimate for the disinfection of sputum and fæcal discharges), indicate that it will be necessary to use some other agent when the object in view is to destroy the infective virulence of tuberculous sputum. And in general it will no doubt be better to use an oxidizing disinfectant, such as the hypochlorite of soda, when the germs to be destroyed are imbedded in masses of albuminous material; for such masses are disintegrated and destroyed by oxidizing agents, whereas corrosive

sublimate has the opposite effect in consequence of its power of combining with and coagulating albuminous material." And yet the Committee has recommended a solution of corrosive sublimate of the strength of two drachms to a gallon of water as equally efficient with chloride of lime for the disinfection of excreta, vomited matters, and sputum. Sternberg himself, in his Lomb prize essay, recommends chloride of lime as the most efficient agent for the disinfection of excreta, and recommends corrosive sublimate as efficient for liquid discharges only. But its value for *this* purpose must necessarily depend on the character of the discharges. If they contain albuminous matter in quantity sufficient to form with the disinfectant a coagulum, they cannot be disinfected by it with any more certainty than can solid discharges. The experimental evidence upon which this recommendation is based will be presented later.

The employment of corrosive sublimate for the disinfection of large masses of material, such as the contents of vaults, cess-pools, etc., is absurd, and would not deserve serious notice were it not for the fact that the report of the Committee on Disinfectants, recommending it for this purpose, has been so widely accepted. But the Committee, in a note inserted after their recommendations were printed, admit that the complete disinfection of such masses is difficult and expensive, and probably impracticable, and insist upon the necessity of destroying infectious material before it is thrown into receptacles of this kind. This admission, however, appears to be based upon impracticability due solely to expense and obvious mechanical difficulties, and not to changes tending to render the disinfectant inefficient. But, if a disinfectant is for any reason inefficient for the disinfection of small quantities of excreta, it is for the same reason inefficient for the disinfection of large quantities. The action of corrosive sublimate upon albumen is, therefore, a fatal objection to its use for this purpose. But such decomposing masses are constantly disengaging ammonia and sulphuretted hydrogen, both of which convert corrosive sublimate into insoluble compounds, and, owing to the high atomic weight of mercury, these gases fix comparatively large amounts of this metal.

Decomposing excreta also contain alkaline carbonates, phosphates, urea, and doubtless many other substances which react with corrosive sublimate and destroy its efficacy, for there is no reason for believing that any of the resulting compounds have any disinfecting power.

It has been suggested, however, that the albuminate of mercury, which is slightly soluble, has germicide and antiseptic powers sufficient to make it superior to all other disinfectants for this purpose, and that this can be relied upon to prevent the development of such germs as are imprisoned within the coagulum of albuminate of mercury. Professor Vaughan, for instance, considers it probable that the value of corrosive sublimate as a disinfectant is due to the formation of this albuminate; and Sternberg, in the *Medical Record* for August 1, 1885, affirms positively that the albuminate is a potent germicide, but gives no facts in support of this statement. Klein's experiments, however, suggest that its germicide power is very slight at the most. Admitting, however, that it has such power, the amount re-dissolved is very small, and this is likely to be converted at once to the inert sulphide by the sulphuretted hydrogen present.

Used as recommended by the Committee, corrosive sublimate is a good deodorizer so far as it goes; but has no more value probably than the ferrous sulphate which it has to a great extent superseded.

If we examine the experimental evidence upon which corrosive sublimate is recommended as an efficient agent for the disinfection of solid excreta, we find that it comprises ten or twelve biological tests made with pure cultures of micro-organisms, or with broken-down beef-tea, or with semi-solid fæces. Some of these were successful, others were failures. It does not appear to have occurred to the Committee that the *nature* of the material acted upon had any influence on the result in the unsuccessful experiments, or that any further investigation was desirable for the purpose of discovering the cause of the failures. But it was assumed that the *quantity* of material was too great for the amount of disinfectant employed, and that, if the latter had been added in larger quantity, or if the time of exposure had been longer, the experiment would have been successful. A liberal allowance was, therefore, made on the side of safety, and a recommendation made accordingly. The evidence upon which corrosive sublimate is recommended for the disinfection of liquid discharges is the following: "The liquid discharges from the bowels of patients with cholera, typhoid fever, advanced tuberculosis, septic diarrhœa, etc., may be fairly compared with our broken-down beef-tea as regards physical and biological characters." The amount required to sterilize a certain quantity of broken-down beef-tea was, therefore, determined, multiplied by two, and the product recommended as efficient for the sterilization of an equal amount of liquid fæcal discharge. A recommendation based upon experimental work of this amount and character is not creditable to a Committee of the leading Sanitary Association of this country, and is not entitled to the favor with which the one in question has been received.

The importance of the disinfection of excreta, etc., cannot be over-estimated. It is conceded that such material must be disinfected before it is thrown into the vault or similar receptacle, because of the impracticability of disinfecting large masses of matter. A disinfectant, to be effective, must have penetrating power sufficient to bring it into intimate contact with every portion of the material to be disinfected. Corrosive sublimate does not have this power, owing to its property of coagulating albumen. It should, therefore, be replaced, if possible, by some agent to which this objection cannot be made. We have such an agent in chloride of lime. It has the power of penetration; it oxidizes and destroys organic matter, and it is, in addition, an efficient germicide, bearing in mind the fact that it must be used in such quantity that it shall be in sufficient excess after the reaction between it and the organic material is complete.

Corrosive sublimate, in a word, though a very efficient disinfectant, as measured by its power to destroy germs, is limited in its applications. It can be used for the disinfection of furniture and other articles made of wood or porcelain, or even metal, if varnished, the floors and walls of rooms, such parts of ships as can be reached with solutions, the hands and the surface of the body, and clothing and bed-linen, if not soiled with discharges; in other words, for the disinfection of surfaces which are not themselves injured by contact with it, or surfaces which do not contain

material of such a character as to destroy its efficiency. Its use for these purposes is, however, very much restricted, because we have no means of disposing of it, except through lead pipes.

Objections have been made to it because of its poisonous character. The danger of poisoning, however, is very slight. The solutions employed are very dilute, and its taste is sufficiently disagreeable to attract attention before an amount sufficient to do any injury has been taken. If the solutions are colored, the danger of mistakes is much lessened. The same objection may be made with equal reason against all substances which we now recognize as disinfectants. Care is necessary in the employment of all of them, and those entrusted with their use should be informed of their properties, that all necessary precautions may be taken.

There is, however, one process of disinfection with corrosive sublimate to which this objection may with some reason be made. I refer to its use for the disinfection of streets, for which purpose it has been employed by the Board of Health of Boston for the past two years or more. If its use for this purpose is continued, the time cannot be far distant when the beds of the streets will become saturated with various compounds of mercury. All of these, so far as we have any knowledge of them, are violent poisons. Is any danger to be apprehended from continually inhaling or swallowing, month after month, dust loaded with compounds of mercury? This is a question deserving serious consideration at the hands of the Board of Health. While not claiming that the process is positively a dangerous one, I believe it is one which involves some risks, and one which it is advisable, therefore, to discontinue.

UTERINE DISPLACEMENTS AND THEIR INFLUENCE ON THE GENERAL NERVOUS SYSTEM.[1]

BY FRANCIS H. DAVENPORT, M.D.

UTERINE displacements have from the earliest times about which we have any medical knowledge been recognized as existing, and as giving rise to disturbances both general and local. It is probable that prolapse and procidentia, as being malpositions which would most quickly and surely be seen, were the first to be diagnosticated and treated. Later, as the vaginal examination became perfected, would follow the forward and backward displacements, reserving for these days of gynæcological enlightenment the recognition of the more refined shades of departure from the normal, which have filled our text books with subvarieties, and for whose relief a legion of pessaries has been invented.

The impetus which has been given to the study of this branch of medicine in the last twenty-five or thirty years has resulted in placing a great deal that is of value on a sound basis. With regard to the special branch of uterine disease which is the subject of this paper, the following may be said: We have learned to diagnosticate the various malpositions to which the uterus is liable, and the tactus eruditus is now seeking new worlds to conquer. Tubes and ovaries whose recognition by a large proportion of practising physicians is still a matter of considerable difficulty are palpated by the trained gynæcologist, and their pathological changes diagnosticated with wonderful ease. The more remote and insignificant structures of the pelvis are now trying in vain to elude the searching finger of the specialist; and in one of the latest text books minute and lengthy rules are given for finding not only the round ligament and ureter, but even for differentiating the various muscles of the pelvic floor, and palpating the pelvic arteries and nerves.

The chapter on the diagnosis of displacements may in a certain sense be said to be closed. So, too, with the mechanical treatment of these disorders. Necessity is the mother of invention, and the skill and perseverance of the gynæcologist in overcoming the difficulties he has had to contend with, have resulted in the multiplication of pessaries of all forms from the external to the intra-uterine, and of substances as various as ingenious, to meet all possible varieties. Slight modifications will continue to appear, but they will be on the lines already marked out, and will in all probability embody no new principle. It is to my mind a fair indication of the feeling which may be supposed to govern the question of treatment in the small proportion of cases which do not show themselves amenable to the mechanical devices alluded to, that progress is in the direction of operative measures, and that too of a bolder character than would have been dreamed of twenty or even ten years ago. Who, for instance, twenty years ago would have thought in his wildest moments of performing laparotomy and suturing the fundus uteri to the abdominal wall to cure an obstinate retroflexion? Yet that has been repeatedly done. It is an outcome to be sure of the feeling of security with regard to opening the abdominal cavity which the splendid results of our leading specialists have developed. Yet still other indications, less striking perhaps, but showing the same tendency, are the Alexander operation of shortening the round ligaments, Säuger's bold procedure of forcibly separating adhesions of the uterus to adjacent parts under ether, or Byford's proposition to shorten the sacra-uterine ligaments by an operation from the vagina.

While such questions as these are, as I have said, practically settled, it is a beneficent law which holds good in any department of human knowledge that it cannot be exhausted. Certain outposts are taken and occupied, and the scene of the conflict shifts to new ground. We know the course which the blood takes in its rapid circulation through the body. We busy ourselves now with counting the millions and billions of white and red blood corpuscles, and noting their varying proportions in disease, or discussing the microscopical character of the membrane which forms the coat of the capillaries. So the question concerning displacements, about which doubt exists to-day, and which are the subjects of discussion, are on entirely different lines from those we have mentioned above.

Curiously enough, one question which it would seem would naturally be the first to be settled, is only recently being met with any unanimity of sentiment. I refer to the normal position of the uterus. It is begging the question to affirm, as some writers do, that an organ, suspended in the pelvis between other organs liable to such temporary variations of size as the bladder and rectum, can have no normal position. On the other hand, it is manifestly absurd to judge a freely movable organ by the same rules as we would a spleen or kidney, and make any deviation from an arbitrary fixed

[1] Read before the Massachusetts Medical Society, June 12, 1888, and recommended for publication by the Society.

standard a malposition. The truth seems to lie between, and the most accurate observers now recognize a normal position of the uterus which varies within certain bounds according to the condition of the adjacent pelvic viscera.

I have said that the question of the mechanical treatment of displacements was practically settled, meaning by that that where such treatment was indicated, the principles on which it would be carried out were essentially known. There still exists, however, great difference of opinion as to the advisability or necessity of such treatment at all. Some writers, a respectable minority at least, maintain that displacements of the uterus very seldom give rise to symptoms, and that when they do general treatment is preferable to local. Still others claim that they are much more often the cause than the result of general conditions, and that not only is it useless to ignore mechanical treatment, but that the best results are obtained by such local treatment either alone or primarily.

These differences of opinion are based upon the different views which are held with regard to the dependence of one upon the other in the question of causation, and their subsequent reaction upon each other. Let me make this clearer by illustration. We find in a given case a malposition of the womb. With it is associated a debilitated state of the nervous system, which shows itself in the protean ways that are so familiar to us under the convenient but vague term of neurasthenia. There is now a problem to be solved in order to arrive at such a correct understanding of the case, that we shall be able to treat it successfully. What has been the sequence of events in this particular instance? Has the general health begun to suffer, the nutrition become impaired, the muscular system weakened, fat absorbed, and as a result the natural supports of the uterus become relaxed, and thus allowed of a version or flexion? Or, on the other hand, has the uterus become displaced, has congestion resulted, followed by a low grade of inflammation, has this begun to react upon the nervous system, and finally resulted in the more or less complete loss of tone which we find in these cases? If we claim that the first hypothesis is correct, our course is plain. Build up the nervous system by rest and tonics, make fat and blood by forced feeding, and as the body becomes better nourished, and the muscular system grows stronger, the uterus will right itself.

On the other hand, if we take the starting-point to be the displacement, our rational plan is to restore the uterus to its normal position, relieve the congestion, diminish the nervous strain, and our patient is cured.

There are to-day firm, I had almost said bigoted, adherents of both these opinions. There are men who make light of the local symptoms of their neurasthenic patients, who claim that treatment of the genital organs rarely does good, and often does harm, and who concentrate all their attention on general treatment. So, too, there are others who refer all these complex and remote symptoms to some lesion of the pelvic viscera, and are content to treat those exclusively. As a natural and almost inevitable result of circumstances, it follows that those who devote themselves largely to gynæcological practice should more often err in the last-named direction, while those who from the character of their practice or from preference see few such cases should fail to give these symptoms their proper significance.

That neither of these extreme views is correct is self-evident. It is, however, insufficient to state in a general way that the advocates of both systems go too far. Little has been done unless such practical considerations are urged and demonstrated, as will set forth in a clear light the true relations which prevail between disorders in the genital sphere, and general nervous symptoms. It will be the object of this paper, if possible, to do this.

There are several questions to be discussed. In the first place we are met at the outset by the inquiry which suggests itself always in considering this subject, is the relation between the genital organs and the whole nervous system so peculiar, that disorders of the latter more often follow disease of the former, than is the case with other organs of the body? The ancients believed it to be so when they attributed to the influence of the womb those nervous manifestations which under the name of hysteria we recognize as a common symptom of a debilitated nervous condition. We now know that hysteria is not necessarily associated with uterine disease, that in fact it occurs in men, yet its preponderance in woman is a suggestive fact. Granted that a woman's nervous system is naturally weaker than a man's, may the cause not lie in the fact that her generative organs during their period of functional activity call for a greater expenditure of nervous force even when in health than any other organ or set of organs? If this is so in health, how much more potent must be their influence when diseased. That such nervous phenomena as we generally call hysteria or the more pronounced condition of nervous debility known as neurasthenia almost exclusively occur between the years of puberty and the menopause, confirms the opinion that there is in the majority of cases a more than chance relation between the disorders of the genital functions and the general nervous disturbance.

The clinical experience of those who have had the largest opportunities for observing these cases, will, I am confident, be confirmatory of this opinion.

There are, undoubtedly, certain classes of pelvic disease which more than others predispose to coincident nervous wear and tear. The amount of pain which accompanies the lesion is one of the criteria by which we judge of the probable effect upon the nervous system. We, therefore, find certain forms of ovarian disease accompanied by dysmenorrhœa very frequently associated with nervous debility. This rule is not absolute, however, for cancer with its gnawing pain does not affect the nervous system in the way that I am describing. It saps the strength and diminishes the vital powers, but it does not make the whole nervous organization hyperæsthetic, if I may so express it. Under this latter condition the nerves respond to the slightest stimulus, even that of a lively imagination, until it needs but a suggestion of discomfort in one part of the body to start reflex symptoms of the most acute type in another. There are certain affections of the female genitals which seem particularly liable to exert this baleful effect upon the whole nervous economy. Some of these have been recognized. Emmet long ago, and many others since then have pointed out the marked results in this direction of a neglected laceration of the cervix. After the primary symptoms of leucorrhœa, backache, dyspareunia, and a feeling of weight in the pelvis have persisted for a longer or shorter time, there are very apt to follow

those phenomena which begin as nervous debility and end as nervous prostration, and these latter symptoms may soon entirely predominate over the former.

This result is more apt to follow if in addition to the cervix the perineum is also lacerated.

Chronic pelvic cellulitis, of which we are hearing less and less, inasmuch as many cases which we formerly classed under this head, are now known to be affections of the tubes and ovaries, chronic metritis, and its result areolar hyperplasia, and even chronic endometritis, all furnish their contingent of neurasthenic cases.

Less, however, has been said about displacements as a cause, and yet I conceive that they not infrequently are the starting-point of grave nervous troubles and serve to keep it up. This cannot be said of all forms of displacement alike, and some consideration of the various malpositions of the uterus with reference to their significance in this respect, is of importance here.

Backward displacements of the uterus are by all means more serious than forward ones. The retroflexions and versions occur oftener, admit of a much greater degree of malposition, and with themselves dislocate other organs more than do the anteversions and flexions. The resulting disturbance to the blood and nerve supply is much more profound. Anteversions pure and simple are in my experience rare, and do not as a rule give rise to symptoms. When, however, with the anteversion there is some descent of the uterus as a whole, a combination which is by no means rare, the resulting effect upon the whole system is much more marked. The same may be said of anteflexion, though here symptoms referable to the bladder and back, and disorders of menstruation are much more common.

Retroversion of the uterus is the most common form of malposition that we meet with, and when of the first or second degree, that is, if the version is not more than one of 90°, it may often exist without symptoms. If the organ, however, is deflected from its normal position in which the long axis of the uterine body makes a right angle with the axis of the vagina, more than 90°, we have symptoms arising from pressure on the rectum, and are apt to have dislocation of other organs. The danger of neglecting the treatment of even the slighter degrees of this displacement lies, as I conceive it, in the fact that as the axis of the uterus approaches that of the vagina, the weight of the abdominal viscera comes directly upon the fundus, and the resistance to descent of the uterus being lessened, slight degrees of prolapse are likely to follow.

Retroflexion adds to the symptoms which it causes in common with the version, those due to the uterus itself being bent, either from a loss of tone of the muscular structure of the organ, or from being drawn over by adhesions. This flexion of the uterus is an exceedingly grave symptom, and productive of the most marked general disturbance. Both for this reason, and because its treatment is often difficult, requiring even severe operative measures for its relief, it is commonly regarded as perhaps the most serious displacement in the category.

Prolapse and procidentia follow closely on retroversion in frequency, and equal if not exceed it in importance. The severer forms of falling, especially when complicated with a rolling out of the anterior and posterior vaginal walls, cystocele and rectocele, are so easily recognized by both patient and physician that their true value as a cause of local and general symptoms is accorded them. Not so, however, with the milder forms, where either from increased weight, or a slight giving way of the natural supports, the uterus sinks a little lower in the pelvis. These relatively minor grades of displacements are very often passed by unheeded, when they in reality are a cause of constant and distressing symptoms. They are not recognized for the reason that in the ordinary method of examination they cannot be detected. With the patient in the dorsal position, the uterus, unless fixed, recedes from the vulvar orifice, and the examining finger fails to detect its abnormal mobility. Even if the patient is requested to strain, the action of the abdominal muscles is not sufficient to force the uterus as low as it descends when the patient is standing, and the force of gravity is added. The proper method of examining in these cases is with the patient standing in the erect position. Then if she is requested to contract the abdominal muscles as if to relieve the bowels, the finger in the vagina will appreciate the full amount of descent.

In the same category, though of less relative importance, are the displacements of the vaginal wall which may occur without any prolapse of the uterus, though their tendency is to produce such in time. They have only recently begun to receive the attention which they deserve.

Lateral displacements are merely subvarieties and minor complications of the forward and backward malpositions which we have spoken of, and do not need any special mention.

From the foregoing it will be seen that the displacements, which most often give rise to serious symptoms and demand treatment, are of the third degree or of lesser degrees when complicated with prolapse, retroflexion especially when bound down by adhesions and prolapse; less frequently anteflexion, anteversion with prolapse, and least frequently of all simple anteversion, and retroversion of the first two degrees.

If we study this order of relative frequency closely, it will be seen that there are three conditions upon which the gravity of the symptoms depends. First, prolapse; second, adhesions; and third, flexion. I have named them in this order because it seems to me that both as regards severity of local symptoms, and secondary effect upon the whole system, especially the nerves, that is the proper order of relative frequency and importance.

I am convinced that prolapse of the uterus, especially in its minor forms, has been much neglected or underestimated as a factor in the pathological significance of uterine displacements. A large proportion of anteversions give rise to no symptoms unless complicated with prolapse; the same is true of many cases of retroversion, and the symptoms complained of in these cases are those characteristic of a descent of the womb, and are relieved by the treatment appropriate to that malposition. A slight amount of prolapse will cause more disturbance with the circulation than a very marked version, and the constant dragging and bearing down, which is the almost universal complaint, is excessively wearing upon the nerves.

The detrimental effects of the presence of adhesions are shown in two ways: first, from the impairment of the mobility of the uterus which ensues; and second,

the production of pain due primarily to the inflammation of the peritoneum, and secondarily to the implication of nerve filaments in the contracting bands of adhesions.

A bending of the uterus upon itself is of importance pathologically for several reasons. The two chief causes, however, to which its effects upon the general health are due, are the interference with the circulation in the organ itself, as a result of which alterations of tissue occur in time, and the displacement of other organs, notably the tubes and ovaries.

Having thus considered in a general way the various malpositions to which the uterus is liable, and the special circumstances connected with the different forms to which their pathological importance is due, it remains briefly to refer to their effect upon the system at large, and to insist upon the necessity of treating them.

I do not by any means claim that uterine displacements are always the primary occurrence, and that they invariably cause grave nervous symptoms. On the contrary, there is that large class of cases of displacement from loss of tone of the uterine supports, where muscular debility is the first factor, and the uterine condition is merely one mode of expression of it. But, even in these cases, the continued presence of the pelvic trouble tends to keep up the condition of nervous debility, of which it may be originally only a symptom.

Of the three principal factors in these cases of displacement to which I have referred — flexions, adhesions, and prolapse — the importance of the first two is, I think, sufficiently recognized by the profession. The *rôle* they play in inducing and keeping up a state of nervous exhaustion is well known. The difficulty here is not that the necessity of treatment is not fully appreciated, but that they rank among the affections of the genital organs which are the most obstinate to yield to the ordinary methods.

Cases of flexions with adhesions were for a long time, and still are by some authorities, considered incurable, and it is the exceedingly unsatisfactory results of the methods of treatment which have been hitherto tried in a class of cases which entails so much local suffering and exercises such a deleterious effect upon the whole nervous system which has led to such severe operative measures being proposed and tried for their relief, as laparotomy, forcibly breaking up the adhesions, and stitching the fundus to the abdominal wall.

It is, however, different with prolapse, especially in the earlier stages. The importance of this has, I am confident, been under-estimated. I claim that is the one element which makes versions, which would otherwise give rise to no symptoms of any pathological significance. The constant feeling of weight in the pelvis, to which is soon added weakness of the muscles of the back and thighs, making locomotion painful, and standing even more difficult, is generally due either to the yielding of the muscular and ligamentous supports of the uterus, or the loss of the integrity of the pelvic floor as a result of parturition.

I would, therefore, urge in all cases where the loss of nervous tone is a prominent symptom, where headache, dyspepsia, inability to walk, sleeplessness following the least excitement, loss of mental power, as shown by the inability to concentrate the mind on any subject, loss of ability to control the emotions, evinced by fits of crying, depression, or temporary exaltation of spirits, followed by a corresponding reaction, where some or all of these symptoms are found, the careful consideration of the accompanying pelvic symptoms, and, if such exist, even though to a mild degree, would recommend a vaginal examination.

If any of the various malpositions be found which have been described in this paper, the important question has to be decided whether it should be treated, and when. If the history of the case makes it clear that it is the primary factor in the case, the first step should be the attempt to cure the pelvic trouble by treatment. The only exception to this rule is in those cases where the general health is so much reduced that the strain necessary to undergo local treatment would be too great. Here attempts must first be made to so improve the nervous condition by rest, food, and tonics, that treatment may be begun. The Weir Mitchell treatment, either thoroughly carried out or modified to suit the individual case, will serve as a model. In cases of this sort, if local treatment is entirely neglected, there may be improvement up to a certain point, but beyond that it will not advance if the special treatment of the genital complication is neglected.

Where the malposition is secondary, if taken in time, local treatment may sometimes be avoided. With the improvement in the condition of the general system, the uterus may recover itself. If it has persisted for some time, however, it in turn becomes one of the causes which keep up the depreciated state of the general health, and must be rectified before perfect health is restored. In these cases of profound nervous debility, every organ and function must be interrogated, and the ability to correctly estimate the pathological significance of the various departures from the normal conditions which are found, and the choice of the order and methods of treatment, is a matter requiring extreme delicacy and skill, and upon it depends the success of the physician.

As to the methods of treatment to be pursued, it is not the purpose of this paper to go into details. A few general considerations may be urged. Malpositions uncomplicated by adhesions or by inflammatory conditions in the pelvis, especially in unmarried women, may frequently be restored to their normal position and a pessary adjusted with a minimum of nervous strain to the patient at one sitting under ether. Where there are adhesions, or even in cases where there are not, but the vagina is narrow, the abdominal walls rigid, and the bimanual method of reposition difficult or impossible, the slower method, by packing the vagina, is to be recommended.

Where the uterus, on examination in the dorsal position, seems normal, but yet the patient complains of symptoms which suggest some displacement, the examination in the erect posture for the slighter degrees of prolapse should not be neglected.

Of especial importance to my mind in this connection are slight tears of the perineum, impairing the integrity of the pelvic floor. These are often overlooked because they not infrequently occur either at the sides where they loosen the attachments of the pelvic fascia, or beneath the mucous membrane in the muscular structure of the perineal body, and the almost intact external perineum gives no evidence of the damage done. These changes, the result of parturition, are a fruitful source of prolapse of both uterus and vaginal

walls, and their repair by a plastic operation will do much toward restoring the general health.

In the obstinate cases of retroflexion, where a pessary will not hold the uterus forward, the Alexander operation of shortening the round ligaments, or one of the other more serious operations, may be considered.

HEBREW PHYSICIANS IN THE MIDDLE AGES.

BY F. B. STEPHENSON, M.D., U. S. NAVY.
Membre Titulaire de la Société d'Anthropologie de Paris.

FROM recently issued publications (Münz, Hosmer) it appears that inmates of monasteries were not the only scholars that made the higher education of Greek and Arab the heritage of modern life. The work of the Jews in this direction is the more striking because of their political and social ostracism. Their personal worth, however, the value of their minds, could not be ignored by the intelligent; and in no field of thought have they won more fame, and thankful recognition among the Gentiles than in medicine. Theological views disappeared when human needs were felt. Pope and prince did not hesitate to follow the advice of Israelitish doctors. The poor were not neglected by them. They served as instructors to those about them. Both Orient and Occident honored them as men and as practitioners. Not only did these people produce an unusual proportion of good surgeons to practice current methods, but through them, at the Renaissance, medicine was revived, to become the parent of physical science in general. In the composite picture presented, we notice a few prominent traits.

Isaac Israeli (obit 950), was a renowned practitioner, and his work "De Diatetica," published among the Arabs, may claim to be of decided value even now. He lived to be 110 years of age, and when asked why he had never married, replied "I have written four books, which will preserve remembrance of me better than children."

Maimonides,[1] in his epistle to the luxurious Sultan, in Egypt, while prescribing for the body, dared to direct the mind toward a rational living.

One ambitious son of Israel, however, a famous doctor, turned Mahommedan; but this change did not bring the desired reputation in a community hostile to those of his original faith; his last days were not peaceful. Another learned one became prime minister of the Great Khan, at Bagdad, and used his power to advance all branches of knowledge; yet envy and ill-will worked his fall. The popular hate toward this race was then (1291 A. D.) the cause of death to many thousands, jealousy, as in our day, being the apparent motive. Moslem physicians generally understood more of astrology and magic then of the noble art of healing, although the Jews, also tried to guide human conduct by stellar positions.

The Hebrew court physicians among the Spanish Arabs did much to preserve and transmit to modern central and western Europe the medical lore of ancient Greece and Rome, though little actual progress in natural or morbid physiology appears to have been made and recorded by them. The contemporary Christian rulers in the peninsula, despite their catholicity, prized the wise sons of David not less than did their Moorish cousins. At the same time, the common folk, similarly to the Islamitic masses, persecuted the "peculiar people," for both religious and economic reasons. A Hebrew surgeon persuaded John II, of Portugal, to refuse aid to Columbus when he asked ships for his voyage of discovery. Cohen and Halevi are names famous for learning and virtue.

Toward the end of the 15th century, a most sad tragedy drove the Judaic people, and with them the physicians, from Spain and Portugal; so that those who, about that time needed a surgeon, were left to the care of quacks and impostors, or found themselves forced to send, at great cost, to distant lands.

Touching central Europe, it is well-known (says Livius Fürst) that, from Charlemagne to Francis First (who requested Charles the Fifth to send him an Israelitish doctor) every ruling prince had a Hebrew as personal physician. The one with Charles the Bald had such a name for magic and witchcraft, that common report credited him with having swallowed up a wagon laden with hay, together with team and driver. Although less advanced and progressive than those of Spain, yet Jewish physicians throughout Germany were fit to be called learned when compared with their Christian colleagues, who knew little of remedial science, and were sunk in ignorance and superstition.

In Ratisbon the inimical citizens complained that almost everybody allowed Israelites to attend them. In various parts of central Europe, from Königsberg (where in 1538, it was unlawful for such to practice) to Strassburg, Hebrew doctors were among those who were first excused from onerous taxes. Import duties on medical books and surgical instruments do not appear as exceptions from such franchise. Will the United States be flattered by comparison?

In Vienna they could not, at one time, be practitioners because of their inability to subscribe to the customary oath, "*de immaculata conceptione:*" in 1517, however, the emperor abrogated this rule. At different times (1373–1567), and in various places throughout Germany, city physicians were employed with definite honoraria. During the 15th century, Jewish women were successful in medicine. In 1419, one received official recognition from the government: about 1430, another was a skilful oculist. Similar instances were not rare, among the Teutons. The renowned John Reuchlin had two Hebrew scholars and physicians as friends and instructors.

In France we find a comparatively larger and more brilliant series of medical men, some of whom possessed the favor and protection of sovereigns, from Hugh Capet to Maria di Medici. Numbers of them were eminent scholars in science, and the ancient literature of physic (translating from Arabic), as well as instructors in medicine to many pupils of the Christian faith, together with those of their own racial descendance.

The Montpellier school, so flourishing in the first half of the thirteenth century, was in great part founded and sustained by them. Nevertheless, one illustrious son of Abraham, in 1288, became a victim of the *auto de fé*, and several were tortured to death on false charges of poisoning.

When, in 1453, the crescent rose above the cross in Constantinople, skill and prudence caused the Hebrew doctors to be trusted and honored by those in power. The influence thus gained was often used to lighten

[1] Dr. Münz, affirming that the industry of Maimonides, as a practitioner and writer of authority in professional matters, has not been justly shown, states his intention to publish a paper thereon.

burdens which discriminating laws put upon their co-religionists. In the latter part of the sixteenth century, the widow of a famous practitioner attended Sultan Mahomet II, sick with small-pox. It is stated that, with her medicaments, she restored him to health, and the grateful patient richly rewarded her. The record does not say that diseases were *self-limited* in those days.

In Poland, a place of refuge when the Jews were driven from Southwestern Europe, intellectual superiority and medical skill procured for them, in many instances, the favor of kings and nobles, and release from the burdens especially imposed upon their people.

It is remarkable that while in outlying territories subject to the hierarchy of Rome the Jews were generally persecuted with vigor, in Italy they lived under more satisfactory relations with the church authorities. In nearly all the larger cities they were active in scientific research, practised medicine, and stood well in the opinion of the Christian communities where they lived. From which we may learn that the laws of physiology (laws of nature, of science, of God) do not show special deference for any particular form of theology. One of these, Leo, had such a good reputation, that, in 1331, he was excused from the Venetian govermental examination usually required. A Mantuan, in 1376, was the first Israelite who printed and published Hebrew books. In his medical works we find ideas that seem quite wonderful, even in the midst of our latest discoveries. Emmanuel, a friend of Dante, like him, wrote an "Inferno," which, in spirit and humor, was equal to that now classic, and in elevation and nobleness of vigor surpassed it. He put the unskilful doctors and quacks in Plutonian regions because they did only harm to human society, and hastened the passage of credulous sick persons to the final sleep. Hippocrates was given a station among the sinners because he held his great wisdom secret, and narrow-heartedly kept his medical books from his fellow-men. In the treatment of exigent patients, Emmanuel was witty and original, often successful; but details are too long for quoting here. A Jew was among the foremost men of the celebrated Medical School of Salerno, which also was indebted to Hebrew scholars for much of the translations from Arabic into Latin there used. At the instance of Charles I, King of Naples, a Jew translated from Hippocrates a treatise on diseases of the horse. One of these doctors is praised by a Christian prince, not only for his professional skill, but because he helped the poor and needy, and was not stern in demanding payment for his services.

Amatus Lusitanus (obit 1592), had a great name as physician. He studied to know the nature or natural history of disease. At the close of a long and busy life he could say that he had never accepted rich gifts, had attended the poor without regard to pay, made no difference between Jew, Christian, or Turk; that neither family reasons, hard journeys, nor anathemas ever kept him from duty. In numerous instances, medicine seemed to be the heritage of families.

Paracelsus is mentioned as one who attempted to reform medicine, which, in his day, was grievously burdened with ignorance and fraud.

One of the recommendations of the erudite Isaac Israeli is that the practitioner should not try to do more than his own health will warrant, because duty requires that he should be well in body and mind in order to properly care for the sick under his charge. Other dicta of this master remind one of the rational practice taught by Hippocrates, Sydenham and Bigelow.

A professor at Montpellier recently wrote that, during the Middle Ages, the practice of medicine was so universally in the hands of the Jews, one might almost think it necessary to be of that race in order to have experience in the healing art. Among them the study of medicine was part of a complete education, often without intention to practice. Their wideness of thought and heartsome sympathy were more conspicuous because of the narrowness of view and fanatic selfishness characterizing the majority of physicians (monks and nuns) in European lands belonging to other cults. No creed or race was debarred from their service. It appears that the very general study of medicine by the Jews of the Middle Ages was due not merely to a desire for knowledge of the truth in nature, but also to a vivid appreciation of its value in religion or ethics, as shown in various codices and pedagogic writings: soundness of body was considered necessary to the manifestation of a virtuous soul. Maintenance of health was regarded a sacred duty by those firm in the faith. They recognized that the perfecting and ennobling of human faculties could be brought about only by the continual application of hygienic principles to the conduct of individual life. The *unpardonable* sins are those which the laws of nature fail not to punish. At the same time, the practice of physic was one of the few modes of life open to them, and the course that gave access to sources of power (kings and princes) for good or ill to their people.

While personal relations with the Jews were often maintained by high functionaries of the Romish Church, canonical censures were repeatedly issued against them; and Christians were threatened with excommunication for calling them to attend the sick, "because," says the edict, "it is better to die than owe one's life to a Jew." Although this sufficed to cause much unnecessary suffering (miscalled martyrdom) and possible death, such logic failed to convince many of those who had need of a physician: the most devout sons and officials of the Church, and zealous preachers frequently complained that the attending medical men in monasteries and convents were generally Hebrews. Sometimes, however, the law was put into effect; for example, in Sicily, during 1293, where the penalty was, for the patient, three months' imprisonment on bread and water; whereas the doctor was given twelve months, his fee going to the poor.

The generalizing of education in modern times has deprived the Jewish scholars and physician of the eminent position held during the Middle Ages. No monuments of brass or marble preserve these heroes' names; no poet sings their fame. The treasures they wrought out lie 'neath the dust of centuries on the forgotten shelves of many an ancient library.

— "Ah, Clara," said a young surgeon (after hospital hours), as he sank upon his knees, "would that I could gain possession of your heart!" — "You can, Mr. Sawbones," replied Clara, promptly but blushingly; "and without giving me ether either." — *New York Sun.*

POSTURAL TREATMENT OF CONSTIPATION.[1]

BY EDWARD T. WILLIAMS, M.D.

A RECENT paper on constipation by an eminent surgeon of this city, and its discussion before the Boston Society for Medical Improvement,[2] embolden me to speak of a source of trouble unnoticed, so far as I know, by formal writers. I allude to a faulty and unnatural posture at stool.

The act of defæcation strongly resembles the expulsive stage of labor. The main propelling force in both cases is the contraction of the diaphragm and abdominal muscles, mere uterine action and intestinal peristalsis playing a subordinate rôle in both acts when physiologically performed.

The importance of posture and other aids in bringing out this natural action of the abdominal muscles in labor is tolerably well recognized by modern writers on midwifery. One often sees women in confinement quit the bed and take up a crouching attitude on the floor, instinctively feeling that they can bear down better in this position. The pulling and pushing movements with hands and feet so universally witnessed are directed to the same end.

Sixteen years ago I had myself the fortune to hit upon a simple and effective contrivance for this purpose which has proved of vast use in my hands. A description of it may be found in the *Boston Medical and Surgical Journal* of June 11, 1874. It consists simply of a twisted sheet with the ends tied together in the form of a ring or loop, in the lower part of which the feet are placed and pushed downwards, while the upper end is pulled upwards with the hands or wrists. It calls the whole set of waist muscles into powerful action, and secures, where the way is clear, a prompt and natural delivery.[3]

But to return to constipation. I feel sure I cannot be mistaken after twenty years' practice, and, I may say, almost daily study of the subject, in thinking that a faulty posture at stool and consequent inertia of the abdominal muscles have been among the commonest causes of the disease in the patients under my care. A gentleman, having finished his breakfast and lighted his cigar, retires, with the morning paper in his hand, to a cosy and well-heated apartment, takes a comfortable seat, and between reading and smoking passively awaits the tardy operation of nature. He either takes no active part at all, or at most inflates his lungs a little and holds his breath, thereby depressing the diaphragm, but having no marked action on the other expulsive muscles — the straight and oblique abdominal, the *psoae* and *quadrati lumborum*. As a result the bowels are imperfectly emptied, a residual mass is left behind in the colon, which, accumulating day by day, must finally be evacuated by artificial means.

Put the same man into the woods, say the Adirondacks. At the call of nature he seeks the nearest thicket, and there assumes a strictly physiological attitude. He neither sits nor stands, he squats. Every muscle of the back and abdomen is brought into play, the bowel is rapidly and completely emptied; and, vacation ended, he returns to his home a new man.

Watch any of the lower animals, the dog, the cat, the pig, the ape at the menagerie, even the horse and cow when hard bound — always an approach to the same attitude. I suppose every one has noticed the same thing in young children.

I believe I need offer no apology for these observations.

We ought, then, to expect, what I have found to be the case, that the assumption of a correct posture at stool would prove a sufficient cure for what may be called passive constipation. The sitting posture should be interdicted, and a stooping one substituted. If the construction of the water-closet does not admit this it should be altered. The margins of the basin should be leaded, and wide enough to afford room for the feet on each side. Above this on hinges should be two covers, the lower one perforated, the upper not. One of the best arrangements, for men at any rate, would be to abolish the seat altogether, and have merely a stone or marble slab, with a hole in it, as is often seen in Europe, at or near the level of the floor.

For ladies the matter is less easily managed. I have often recommended the use of the chamber utensil instead of the ordinary seat. One lady of most distinguished family and position assured me that this was one of the most valuable suggestions she had ever received. I have found it equally beneficial in other cases.

I have now been using and recommending this posture treatment for twenty years. I hardly know any person of sense who ever properly tried it who did not find it of advantage. With proper diet and exercise it will surely cure the majority of cases with comparatively little aid from medicine. Still drugs and clysters are needful at times, and in certain cases must be regularly used: though I believe the greater part of those who require continuous dosing are persons too ignorant or too indifferent to try and cure themselves by natural and simple means. The abused motto, *natura duce*, too often made a mere cloak for professional ignorance, here finds a wise and wholesome application.[4]

[1] Written April 20, 1888, and read before the Massachusetts Medical Society, June 13, 1888.

[2] See Boston Med. and Surg. Journal, April 12, 1888, pp. 376-378.

[3] The description of what I call my "birth-sheet" was printed under the misleading title of "A Substitute for the Binder," a title prefixed by editorial oversight to a brief note without title. Doubtless I was to blame myself for not giving the note a title descriptive of its contents, but the the error was peculiarly unfortunate as tending to divert rather than attract attention to a contrivance which in my own experience has saved a deal of operative interference and a goodly number of human lives.

[4] Since writing the foregoing paper, in fact since the printed programmes of this meeting were issued, my attention has been called to two articles on the same subject, one by Dr. A. W. Abbott, of Minneapolis, in the *Northwestern Lancet* of March 1, 1888, the other an editorial review of Dr. Abbot's paper in the *New York Medical Record* of May 12, 1888.

I have decided, notwithstanding, to read my own paper as I wrote it, without entering into any question of priority with Dr. Abbott. While he certainly has the honor of being the first in print, I can positively prove that my practice antedates his paper by an even score of years, and has been liberally recommended to patients and physicians ever since. It was my experience of the benefits of this practice which first suggested to my mind the conception of the "birth-sheet" previously described, which I commenced using in 1872, and published in June, 1874. On May 23, 1878, I explained in full detail my notions on the posture treatment of constipation before the Roxbury Medical Improvement Society, as can be clearly substantiated by the official records, and the recollection of members present at the meeting. The present paper was inspired by the one of Dr. R. M. Hodges previously alluded to, at a time when I was as yet totally ignorant of the already published article of Dr. Abbott. Yet there can be little doubt that the posture here advocated on scientific ground is habitually used by great numbers for convenience' sake, and has been used by the majority of the race from the earliest period of its existence on earth.

— Mr. W. J. Clapp gives in the *Lancet* for July 21st, details of a case of tetanus successfully treated by him with the tincture of strophanthus, and administered in the form of tabloids containing two minims each, given every three hours. In a fortnight the man was able to walk and eat as usual, and subsequently returned to his work, quite well.

REPORT ON PHYSICAL CULTURE IN SCHOOLS.[1]

BY Z. B. ADAMS, M.D., E. H. BRADFORD, M.D., AND C. F. WITHINGTON, M.D.

THE Special Committee of the Massachusetts Medical Society appointed at the annual meeting, June 8, 1887, "to investigate the subject of Physical Culture in Schools, and to report on the same at a future meeting," beg leave to present the following report, in which they would call the attention of the Society:

(1) To the need of some method of Physical Culture, particularly for the children of our cities and larger towns:

(2) To what has already been accomplished in some quarters in the direction of supplying this need; and

(3) To a brief consideration of what seems to be practicable for schools (and particularly the public schools) to undertake for the physical training of their pupils.

I. THE NEED OF PHYSICAL CULTURE IN PUBLIC EDUCATION.

Were intellectual achievement the sole legitimate aim of education, a position which we protest against as partial and false, it would still be true that in the interest of purely mental development, physical well-being is indispensable. The brain is composed of material tissues, and its functions cannot be long or successfully maintained, unless those tissues, together with the body of which they form a part, are in a state of physiological health. Despite sporadic cases of an active mind in a feeble body, it is true that sustained and successful brain-work can be done only by a well-conditioned organism. The world is awaking to the fact that as mortification of the flesh does not conduce to moral health, neither will an overworked and ill-nourished body sustain a valid mind.

But it is not alone mental strength which is needed for successfully wrestling with the world. For the more highly educated, and still more emphatically for the children who receive their only preparation for life in the public schools, it is true that much besides what is learned from books is necessary for success in life. It is here that the current systems of education most seriously fail. They have occupied themselves solely with the mind, and have left other fields, equally or more important in their possible fruition, to lie fallow. No child will achieve his best usefulness whose moral and physical powers are left uncultivated. "Teach my boy three things," said an old-time father, "to ride a horse, to shoot a gun, and to tell the truth." Such acquirements as these made the fathers of the State, and while we can to advantage add to them in our modern education, we cannot dispense with them. Manual training has only of late begun to find a place in our school-rooms. It should be welcomed by physicians as well as by sociologists. Apart from the direct utility of sewing and cooking for girls or of the use of tools for boys, there is a physical advantage in the training of groups of muscles to coördinated action; and disciplined muscular action is itself no slight stimulus to the brain.

The time has come, in our judgment, for a further extension of this principle. Not only the brain, but the eye and hand, and not only these but the whole muscular system should receive a training, which will make the individual efficient in whatever field he elects to work.

The splendid results attained by those nations which have paid especial attention to the cultivation of the body are too well-known to require extended reference. It needs no medical eye to see in the pale skins, narrow chests, thin and nervous frames of the great mass of public-school children in our cities a sad contrast to that physical perfection which gave to ancient Greece her leadership in arms and in art. A competent authority on the subject, and an American as well, says that one can enter the public schools of New York city and easily separate the German children from the American, simply by the difference in physique, the former class having had the advantage of the training of the Turners' societies, and the latter having grown up without any physical culture whatever.

We are in danger of forgetting the great changes in the condition of American life which have taken place in the last forty or fifty years, changes which require a general re-shaping of our habits. In former years a much greater proportion of the population lived in the country; boys and girls had an abundance of out-door life. The open air was their gymnasium and the apparatus was whatever implement of labor they were required to wield. The apprentice system had not died out and the native-born population did not think it beneath them to learn trades, which were in themselves an education to body and to mind. Now it is estimated that one-fourth of all our children are living in the large cities of the country. While many of the cities are growing with marvellous rapidity, the country districts, at least throughout New England, are not holding their own. It is said that while a half century ago 85% of our male population were engaged in farming or other out-door work, not more than 40% are so engaged at the present time. Town-bred boys have no wood to chop, and except as they have access to public parks, no fields to play in. Out-of-door play for girls is quite obsolete. Brick sidewalks and brick school-yards are discouragers of running and romping, and the child of the period, especially if a girl, settles down early to the staid gait of its elders.

"The first requisite to success in life," says Herbert Spencer, "is to be a good animal. The best brain is found of little service if there be not enough vital energy to work it." Preventive medicine, public hygiene and orthopædic surgery, while they have rendered inestimable benefits to the State, have yet kept alive many of those weaklings, who under the operation of the law of the survival of the fittest, would have perished. These defective individuals, added to the general sum of the adolescent population, tend to lower the average of physical excellence, and while merciful science has saved many a life otherwise doomed, she must see to it that her kindness to the individual do not carry with it a peril to the vigor of the species. Physical culture is necessary as never before, to meet the artificial conditions of urban life, and to prevent the feeble organizations from perpetuating their own type in their descendants.

II. WHAT HAS ALREADY BEEN ACCOMPLISHED FOR THE PHYSICAL CULTURE OF THE YOUNG.

In studying how to inaugurate any needed reform it

[1] Report presented to the Massachusetts Medical Society at its annual meeting, June 13, 1888, accepted by the Society, and ordered to be presented, with its endorsement, to the Massachusetts State Board of Education.

is of value to know what results have been arrived at by others working at substantially the same problem. The success of physical training as an integral part of public education in Germany is too well known to require extended mention. We would remark, however, that it was advocated in June, 1842,[2] by Frederick William IV, and with considerable promptness carried into partial effect. In 1860 it was introduced into the elementary schools for boys. In 1862 it was made compulsory, and more recently has been introduced generally into girls' schools. It is now required of each scholar for two hours per week. The exercises are graded in difficulty according to the age of the pupils from six years upward. Berlin in 1885 contained ninety-eight turnhallen, used for educational purposes. Frankfort expends yearly $27,000 for the physical culture of her 18,000 public school children, and Vienna for her schools about $35,000, or one-twenty-ninth as much as her total educational outlay.

The German Turners' Association, which have been so closely identified with the cause of physical culture in the mother country, are continuing their good work in the land of their adoption. Last year the North American Turnerbund had under gymnastic training nearly 19,000 boys and girls, the children of its members.

In the observation which your committee has been able to make of these gymnastic classes, they have been impressed with the usefulness of the work done. The drill is for the most part conducted in the turnhallen, of which there are in the country 144, costing some $3,000,000, belonging to the local societies, and the children have the opportunity of using such of the "heavier" apparatus as is adapted to their years; as, for instance, rings, ladders, and, to a moderate extent, high bars. But the latter appliances your committee does not consider essential to the training of young children, when the free movements and light gymnastics are so easily attainable. The German system has brought into our land an impulse in the right direction, physical results which form an impressive object-lesson in comparison with our present generally do-nothing policy, and the Turners' Normal School for training gymnastic teachers may possibly be made use of in securing instruction to our public-school teachers for the work which should be made a part of their pedagogic duties.

But the Germans are by no means the only ones who are alive to the needs of bodily training. The physical renaissance has begun in good earnest in most of our American colleges, while athletic clubs and gymnasia include many of the young men in the well-to-do classes of our city populations. But the movement which has well begun at the top of our educational system, needs to be extended downwards through all its ramifications. The great mass of children never reach the upper grades even of the public schools. If such children are to receive any physical culture whatever, it must be in the grammar, the intermediate, and even the primary schools.

In the "preliminary" schools, those having pupils from sixteen to seventeen years of age and under, is the present need of pioneer work. And here, we are happy to note, already pioneers are not wanting. As might be expected, the private schools and endowed academies have been among the first to secure the requisite funds for such instruction. The report of the New Hampshire State Board of Health for 1887 contains an article by E. H. Fallows, reviewing the present status of physical education in public and preparatory schools. It is, unfortunately, incomplete in its data, but, so far as it goes, its information is valuable and interesting. In 60 out of 118 schools of this character which have answered the queries of this investigator, a gymnastic drill of some sort or other is required, but in half of them it is pursued at such long and irregular intervals as to be of little use. Among the 118 schools there are 27 gymnasia, and 28 rooms more or less extensively fitted up with apparatus. The total outlay for gymnasia and rooms was about $115,000, and $65,000 of this amount is represented in the gymnasia of three academies, namely, Phillips (Andover), Williston and Phillips (Exeter). These 118 schools are, of course, but a small part of all the schools of their kind, though they include many of the best known public and private institutions in the country, and doubtless represent an amount of attention to physical culture much greater than would be found in all the schools taken together.

We know of some schools not included in this list which are doing excellent work, and, on the other hand, some of the gymnasia reported in this list we have reason to know are rendered worthless or even worse to the pupils through lack of any skilled supervision in their use. The amount laid out for a gymnastic "plant" is no criterion of the usefulness of the work accomplished, a simple room with a very slight apparatus, or even none at all, having, under intelligent direction, greater capacity for good than the most elaborate appliances without it.

In only five of the schools referred to are physical examinations and anthropometric measurements of the scholars made the basis of the training. These are the Adelphi Academy, of Brooklyn, N. Y., the Preparatory School, at Princeton, N. J., the Wesleyan Academy, at Wilbraham, Mass., the Hill School, at Pottsdam, Penn., and the Phillips Exeter Academy, at Exeter, N. H. Each student is examined physically and measured once a year, the measurements being in accordance with the system used by Dr. Sargent in the Hemenway Gymnasium at Harvard, and Dr. Hitchcock, at the Pratt Gymnasium, Amherst, and adopted by the Association for the Advancement of Physical Education. A handbook of developing exercises is made out in accordance with the needs of the individual and given to each student. It contains, also, special instruction regarding air, hygiene, food, bathing, clothing and sleep.

It may be said that the responsibility of a boarding-school for the physical welfare of the pupils is greater than that of a day-school in which the pupils dwell under the parents' roof. But obviously the parent's responsibility is limited by his ability, and if the circumstances of his life in a narrow city quarter render it impossible for him to give his child any chance for a sound physical development, the municipality must look to remedying the defect or it will not be remedied. Certainly as a measure of public policy the State can as ill afford to neglect the bodies of her future citizens as their minds. It is, of course, not to be expected that the public schools can so far individualize its work in this direction as the private schools. In

[2] For this and other facts regarding the school gymnastics of Germany, see Physical Training in American Colleges and Universities, by E. M. Hartwell, Ph.D., M.D., of Johns Hopkins University. Circulars of Information of the Bureau of Education. No. 5, 1885.

the former the pupils must be exercised in classes; and anthropometric measurements, if made, will be more useful in showing the adaptation of the system to the needs of the average pupil than in affording a treatment for the special abnormalities or deficiencies of the individual.

In 28 of the 118 schools above referred to, a military drill is used. In 15 this is accompanied by light gymnastic work, but in the other 13, as the report says, with perhaps unnecessary severity, "nothing is done for the physical welfare of the pupils." A much larger number of schools in reality are depending upon military drill as the only means for physical culture of their pupils. It is probably better than nothing for this purpose, and if practiced without guns, or with a wooden gun of weight adapted to the strength of the pupils, would be much more useful than it generally is at present.[3] The system, as it exists, however, in many of our large towns, we consider productive of little good for the outlay involved, which is considerable, both to the public treasury for the guns, and to the private pocket for the uniforms, while it is applicable to only a small portion of the children needing physical training.

A word in passing regarding the results attained by systematic training in calisthenics and light gymnastics in a private academy, the Adelphi, of Brooklyn. The director of physical culture, Dr. W. G. Anderson, in his report for 1886 gives the measurements, height, weight, etc., of his pupils, and, for comparison, those of average Boston boys and girls in the public schools, taken from Dr. Bowditch's report, and also the measurements of selected boys from the Boston Latin School and the Massachusetts Institute of Technology. The tables show a considerable difference in favor of the former, which, while it may be in part due to more favorable social circumstances, is yet, in the opinion of the director, chiefly due to the daily drill in light gymnastics which is carried on with much thoroughness.

But while endowed schools are often in position to afford gymnastic outfit which is not attainable for public schools, your committee are glad to observe that the latter class have already, in several instances, demonstrated their capacity for doing this work, which must be done for the great mass of our city children, if at all, by the public schools.

Kansas City has taken a most advanced position in the line of public physical training. The work has been, since its inception in October, 1885, under the charge of Mr. Carl Betz, who has published a series of manuals of free gymnastics, of gymnastic tactics, and of light gymnastics (with poles, dumb-bells, rings, wands and clubs), with which he has kindly furnished your committee. The method is based on the German system (Turnkunst), with special adaptation for use in the common-school system of America. This system was, in September, 1886, adopted by Chicago for her public schools. The work there is under the direction of Mr. Henry Suder. Eight teachers are employed, who visit each grammar grade twice a week. On the other days the regular teachers give instruction in the exercises. A pamphlet containing lessons for each week of the school year has been printed for the use of the teachers. The same system has also been introduced into the public schools of Yankton, Dakota, Slater, Mo., and Davenport, Iowa, while we learn that a beginning was also made last year in Louisville, Cleveland, Omaha and Denver.

Mr. Betz's report on this method of his work in Kansas City after it had been fifteen months in successful operation, is as follows:

"On every Saturday the director of physical training drills the principals of the different ward schools. These in turn drill their assistants, the regular teachers, on every Monday. The assistants take up the new drill for the week on every Tuesday. The drill is obligatory, and is taken as any of the other studies. At 10 o'clock A.M. all principals strike a gong, and at this signal all teachers take up the drill at once (daily). Thus at the same time all school-children throughout the city have the same exercise. Each teacher is furnished with a manual of instruction, which clearly marks the work to be accomplished. The scholars, of course, do not leave the school-room. The assistant teachers are required to make a daily report of the work, and at the end of each school week hand them to their respective principals. The principals make a monthly report to the director, who reports on the entire work to the board. As yet we have only free gymnastics, but as soon as possible dumb-bells, wands, poles, rings and clubs will follow. Then gymnastic games and popular gymnastics will be taken up, and lastly heavy gymnastics on apparatus."

While the western cities as above mentioned have, perhaps through the prominence of the German element in their population, been the first to provide systematic physical training for the public schools, your committee recognize with satisfaction the work which is being quietly done in isolated instances by public school teachers nearer home. The school committee of Boston have for many years past in their schedule of studies for grammar and primary schools, appropriated ten minutes a day for "physical exercise," but without any definite instruction as to how that exercise shall be taken. Deprived of any active interest or encouragement from the authorities, the work cannot be said to have amounted to much in the schools at large, but in a few instances, where teachers themselves have been interested in the subject, the permissive attitude of the authorities has been made use of to good purpose.

Scholars and teachers have, in some instances, by their own contributions, purchased light apparatus, such as dumb-bells, wands and rings (for the city has never made any outlay for such purposes), and the apparatus has been virtually presented to the city by these enthusiastic workers for the benefit of future users.

With no intention of reflecting upon the work done elsewhere, we wish to speak with special approval of the exercises as conducted at the Prince School in Boston, the Dillaway School in Roxbury, and the Chapman School in East Boston. The plan pursued differs in each of these schools, being in each case the product of the intelligence of some one enthusiastic teacher, working upon the problem as it presented itself to his or her mind. In one of these schools the drill now in vogue was planned by Miss Allen, at that time a teacher in the school, and now in charge of the successful gymnasium for women in Boston. The en-

[3] In the Berkeley School, in New York, where the military drill exists at its best, the "Martini tactics" are employed, thereby avoiding the unphysiological and largely one-sided manœuvres of the common, or Upton's tactics, and the guns for boys from fifteen to eighteen years weigh not exceeding four and one-half pounds; for ages under fifteen from two to three pounds.

thusiasm aroused by an earnest teacher in a school is most remarkable, and outlasts the personal presence of its inspirer. In all the schools referred to, the work is heartily sustained by the teachers as a body, who, so far as is known, are unanimous in their praise of the good results obtained. Inquiry shows that where thus practised, it is popular with scholars and parents alike. Of course, in schools where there happens to be no teacher who takes much interest in the subject, there being no general and uniform plan prescribed by the central authority, the pupils receive no physical culture worth speaking of. In saying that the city of Boston has expended no money for apparatus for Grammar schools, we do not, of course, forget that it has laid out some $1,500, chiefly upon heavy apparatus for a gymnasium in the English High School building, an expenditure rendered nugatory by the lack of an instructor in the safe and proper use of the apparatus, nor that it has spent for guns for the use of the High School boys a sum much larger than would be needed to supply enough light apparatus for all the school-children of both sexes.

III. WHAT IS FEASIBLE IN A SYSTEM OF PUBLIC INSTRUCTION.

It is to be borne in mind first and always that what is aimed at by physical education is not the production of athletes, but such a development and training of the body as shall make it a healthy organism, able to accomplish all that may be reasonably required of it.

Most of our modern school-houses in the large cities and towns, have a general "hall" in which the seats are movable, and which can be cleared so as to give room for the requisite manœuvres. Some of the buildings have specially designed drill-halls. These rooms are large enough for classes of twenty to fifty to march, and to go through free exercises and light gymnastics without collision. For a very small sum, a few sorts of apparatus could be provided, in quantity sufficient for the use of one class at a time, and capable, of course, of being consecutively used by many different pupils daily. The music, which is so important a factor in regulating the rhythm of concerted movements, can be readily supplied by the piano, which every city school possesses.

As to the particular system of exercises to be followed, we need not go into detail. Whether the German or the Swedish method is to be preferred, is perhaps a matter for further investigation. But the system must be one that is simple, and not dependent on expensive appliances. It must be interesting. It must call for alertness of attention and promptness to obey command. It must involve movements in unison with other persons, both stationary and in marching. It must combine these good points of the military drill with bilateral and free, instead of unilateral and cramped movements. It must be equally available for both sexes, and with modifications for all ages.

The matter of instruction in physical culture is one of great importance, and this will require the employment of persons who are qualified by study and experience to adapt the work to the needs of the pupils. But there is no reason why the regular teachers in the school cannot, after being instructed in the principles and practice of the science, carry on the work of their own classes under the oversight of a general supervisor of physical culture, in much the same way that some of the teaching of music in our schools is now carried on. This will make the expense of the movement, after the first, comparatively light. We understand even, that the cost of establishing the system in Kansas City was only $1,300 a year and in Cleveland $1,600.

In conclusion, we beg leave to mention that action looking towards supplying the needs above referred to, has already been taken by three of the district societies represented in this parent organization; namely, the Suffolk, the Middlesex, the South, and the Norfolk District Societies, by the appointment in each case of a committee on the subject. That the American Association for the Advancement of Physical Education, at its annual meeting, held at Brooklyn in November last, unanimously adopted resolutions as follows:

Whereas, A rational, harmonious system of education affords the best and surest guaranty for the welfare and stability of a republic;

Whereas, The present system takes into consideration the training of the mind only, almost totally neglecting that of the body;

Whereas, It is now universally conceded that physical training is a most essential factor in the education of the child with reference to his intellectual, moral and physical nature; and

Whereas, Physical training has been introduced into a great many schools of our country, and wherever introduced has given the utmost satisfaction; be it

Resolved, That the Association for the Advancement of Physical Culture, recommend to all the Boards of Education in this country, to embody Physical Culture in the course of study of the schools under control.

We recommend that this Society, approving the spirit of the above resolutions, present them with the foregoing report, to the Massachusetts State Board of Education, and respectfully, but earnestly urge upon that body such action as will bring this important subject to the favorable attention of local schoolboards in the towns and cities of the Commonwealth.

Reports of Societies.

CONGRESS FOR THE STUDY OF TUBERCULOSIS.

HELD AT PARIS, FRANCE, JULY 25–31, 1888.

THE first session of this important gathering whose recent organization, with Chauveau for President, Verneuil and Villemin for Vice Presidents, is one of the indices of the progress of the age in experimental pathology, was held in the amphitheatre of the *École de Médicine*, Paris, July 25th to the 31st ult. There was a fitness in the election to the highest office in this Congress, of two men who have done so much to advance our knowledge of the true nature of tuberculosis; Villemin, who may be said to have been the pioneer in researches of this kind, having been the first to prove the infectiousness of tubercle; and Chauveau who was the first to confirm Villemin's discovery, to demonstrate the transmission of tubercle by the digestive passages, and show the difference which exist between true and false tubercle.

The work of the first day consisted in the opening address by Chauveau, in which he gave a history of the recent researches which have led to the present doctrine of the infectiousness and microbic nature of tubercle. The identity of human and bovine tuberculosis, and that of other animal species is now every-

where admitted, and the notion, now proved true by innumerable experiments of the transmissibility of this disease from one species to another, has been fruitful in practical consequences. It is on this account that veterinaries and physicians are forming associations to find out what measures may be adopted to preserve society from this dire scourge.

M. Cornil, whose labors in pathological histology are so well-known, read a paper

ON THE TRANSMISSION OF TUBERCULOUS INFECTION BY THE MUCOUS MEMBRANES.

In order that the tubercle bacilli may penetrate the tissues by the mucous surfaces, it is not necessary that the latter should be the seat of lesions, excoriations, or fissures. Chauveau, Villemin and Bollinger had determined tuberculous intestinal lesions in animals which had ingested milk containing bacilli, and even the cultures of these bacilli. Tappenier, Schottelin and Theon have also caused the production of tubercles in the lungs, by making animals inhale liquids holding tuberculous matters in suspension. Cornil has witnessed the development of tubercles in the uteri of hares, in which he had introduced a few drops of the culture of tubercle bacilli. These were visible after twelve days, and after thirty-two days the lesions had spread to the neighboring tissues. This inoculation was produced without the least abrasion of the epithelial covering, which often remained intact, despite the continuous development of tubercle granula.

Cornil has seen tuberculosis in the human female localized in the cervix uteri, with the lesions of chronic catarrh, and tubercle granules with giant cells below the intact epithelium.

M. Nocard, of Alfort, read a paper on

THE DANGERS ARISING FROM THE USE OF MEAT AND MILK FROM TUBERCULOUS ANIMALS.

There is no doubt as to the possible contamination by bacilli of milk. As a certain percentage of milch cows are tuberculous, it is expected always to boil before using it, the milk served in cities. The sale of milk from cows known to be tuberculous, should be absolutely interdicted.

The same may be said of meat, though the juice of flesh of tuberculous animals, is rarely capable of determining tuberculosis. Out of forty guinea pigs which Nocard had inoculated with one cubic centremetre of the juice of meat from tuberculous cows, only one became tuberculous (succumbing fifty-seven days after the injection). It seems, then, that in some rare cases tuberculosis is a disease *totius substantiæ*, but this generalization of the malady is but transient, the blood and muscular juice very rapidly ceasing to be virulent. Experiment on cats (an animal known to be susceptible to tuberculosis) which were made to ingest tuberculous meat, and not one of which became tuberculous, have shown the comparatively little danger there is from this source. Cooking, moreover, of course renders such meat much less virulent.

The greater part of the following day (July 26th), was devoted to the discussion of the paper of M. Nocard. During this discussion many important facts were brought out. Baillet, of Bordeaux, thought that the meat of tuberculous animals played but a trifling rôle in the transmission of tuberculosis to man: thus, at the slaughter-houses of Bordeaux, out of 22,000 head of cattle only 40 were found which were tuberculous; by the side of this small number of sick animals, the official statistics give 1,000 phthisical persons to a population of 250,000. It would seem from this that the influence of diseased meat on the propagation of tuberculosis in the human race plays a decidedly secondary rôle. M. Spellmann, of Nancy, said that tuberculosis was very frequent in the stables of Hautes-Vosges, the mortality of cows from phthisis being thirty to forty per cent. The meat of these animals, bought at a low price and offered for sale in the neighboring towns, constitutes a permanent danger of infection.

Guiraud, of Montanban, stated that at Montanban it had been found that there was one phthisical animal to every 245 head of cattle; while Villain, of Paris, said that in the metropolis of France the proportion of phthisical animals is 6 per 1,000, at least, for the abattoirs of Villette and of Grenelle. Thomassen, of Utrecht, (Holland), gave some statistics as to the prevalence of tuberculosis among cattle in Holland; this is one-half per cent. With respect to swine, the percentage is somewhat higher. Liegen, of Luxemburg, had succeeded in tuberculizing four hogs by giving them meat to eat from a tuberculous cow. Robinson, of Grenock, Scotland, spoke in favor of a total interdiction of tuberculous meat. Guinard, of Dijon, alluded in severe terms of condemnation to a custom prevalent in some localities among anæmic patients, of resorting to the abattoirs to follow out a line of treatment which consists in drinking the blood of an animal just killed.

The Congress voted a resolution condemnatory of the use of all meats from tuberculous animals and recommending the seizure and destruction of such animals, but a principle of indemnity to the owners was also recommended.

At the evening session, July 27th, M. De Brun, of Beirut, gave an address on

PULMONARY TUBERCULOSIS IN SYRIA.

Formerly phthisis was rare in Beirut when malaria was rife. Latterly, the marshes have been drained and rendered salubrious, the land cleared and cultivated; the result has been a comparative disappearance of the malaria, but at the same time phthisis has appeared and is now making ravages among the population. The often alleged antagonism between tuberculosis and malaria thus seems to find exemplification. Observations made in other parts of the East and in Egypt, agree perfectly with the facts noted by Dr. De Brun in Beirut. The climate of Syria, on the whole, seems particularly favorable to the development of phthisis, which prevails in an especially rapid form wherever malaria has not already had the ascendency.

MM. Chautemesse and Widal, of Paris, made a communication on

THE PERSISTENCE OF THE GERMS OF TUBERCULOSIS IN RIVER WATER.

The results of an elaborate series of experiments were these: that the germs of tuberculosis remain alive for fifty days in Seine water sterilized and kept at a temperature between 8° and 12° C., and seventy days in Seine water kept at 15° to 18° C. This is one aspect of the question; another series of experiments show that they do not preserve their virulence or, if at all, to a very feeble degree, the result of inoculation of this water in animals being *nil*.

On the other hand, Galtur and Cedeac have been more successful with their inoculations of tuberculous matter kept in standing and in running water. They placed fragments of tubercle in water that was incessantly renewed, and other fragments in standing water, then cultures were attempted with these liquids. The running water gave positive results from inoculations a month and a half after the beginning of the experiment, while the stagnant water was inoculated with success one hundred and twenty days afterwards.

M. ARLOING made a report

ON THE LOCAL AND GENERAL MEANS CAPABLE OF ARRESTING THE EXTENSION OF EXPERIMENTAL TUBERCULOSIS.

He first endeavored to arrest the march of tuberculosis in the same way as some have proposed to stay the progress of syphilis, by the extirpation of the local lesion and the neighboring glands. This is an experiment which is quite easy of execution in guinea pigs, where the inoculation is made in the mammary gland. All the animals that were the subjects of this early extirpation of lesion and glands were found, on killing them after a certain number of weeks, to be tuberculized to the same degree as an equal number of animals, which were inoculated at the same time, but without subsequent extirpation of the primary centres of infection. In a second series of experiments he practised the excision at the point of inoculation on the sixth day, when there was no swelling to indicate the success of the inoculation, but the tuberculosis none the less pursued its course and became general. He also tried the inoculation of what he supposed might be *attenuated virus*, that is, scrofulous matter; but "alongside of a positive scrofulous inoculation," he found that he could succeed perfectly with "an inoculation of true tuberculous virus, capable of producing the disorders of tuberculosis." Cornil and Babes had previously published results of this kind. Finally, thinking that the action of certain antagonistic microbes might neutralize the morbid effects of the tuberculous virus, he attempted in guinea pigs the inoculation of typhoid fever virus, but found "that the animals the most saturated with typhoid virus were still perfectly susceptible of contracting tuberculosis," and were in no degree exempt by being victims of another infection.

THE BACTERIAL ASSOCIATIONS OF THE TUBERCLE BACILLUS.

M. BABES, of Bucharest, read a paper with the above title. In certain diseases, and especially in localized affections, such as tuberculous arthritis or osteitis, there exists an intimate association between the specific microbes of tuberculous and other microbes. The tuberculous lesions open the way for other bacteria which remain distinct from Koch's bacillus or form with it special products. In these cases this composite microbe is found in more or less intimate relation to the tuberculous products. These foreign microbes are often instrumental in awaking to activity a lateral tuberculosis.

M. DURET, of Lille, spoke of

GLANDULAR TUBERCULOSIS.

Tuberculosis of the glands comprehends three clinical forms, each demanding different treatment: (1) The fibro-caseous form; (2) the caseo-tuberculous form; (3) the ulcerative or fistulous form.

In the fibrous form, the only rational method is extirpation. The second form demands igni-puncture or crucial cauterizations. The third form is best treated by the thermo-cautery, which should be pressed down to the bottom of the suppurating cavities, with thorough destruction of the fistulous tracts.

ON PSEUDO-TUBERCULOSIS IN MEN AND ANIMALS,

This was the subject of a communication by MM. CORNIL and TOUPET. The pseudo-tubercle may be anatomically undistinguishable from the true tubercle, and may contain giant cells, but it is free from the bacilli of Koch, and does not produce tuberculosis in animals.

M. HUREAN, of Villeneuve, spoke of the

USE OF RAW MEAT,

but in condemnation of this kind of aliment.

M. REDARD, of Paris, spoke of

SURGICAL INTERVENTION IN TUBERCULOUS OSTEO-ARTHRITIS OF THE TIBIO-TARSAL JOINTS AND OF THE FEET IN CHILDREN.

These can often be cured by free opening of the joints, followed by curetting or scraping, and cauterization with the thermo-cautery. The tuberculous foci must be carefully disinfected before and after the operation; there must be thorough cauterization of all the tuberculous *foyers* and fistulæ, good drainage, prolonged antiseptic baths, and immobilization by plaster or silicate splints. The results of such operative surgical interference have been almost invariably good.

The third day was largely taken up by a discussion of the question of

THE HUMAN RACES, THE ANIMAL SPECIES, AND ORGANIC ENVIRONMENTS, CONSIDERED FROM THE POINT OF VIEW OF THEIR APTITUDE FOR TUBERCULOSIS.

The subjects of

HEREDITY OF TUBERCULOSIS IN ANIMALS

and of

TUBERCULOUS CIRRHOSIS

were taken up in their order.

At the evening session there was an interesting discussion on the third question:

THE WAYS OF INTRODUCTION AND PROPAGATION OF THE TUBERCULOUS VIRUS IN THE ECONOMY; PROPHYLACTIC MEASURES.

Tuberculosis is rarely transmitted by subcutaneous inoculation. A dissection wound has rarely, if ever, caused tuberculosis, and the same may be said of wounds received at the autopsies of phthisical persons. There may be a painful tumefaction at the point of the lesion, followed by abscess, but the local tuberculosis gets well without becoming generalized. There, however, are exceptions to this rule, and instances were cited where generalized infection and death have followed a wound received at the autopsy of a tuberculous person. Some interesting facts were given to show the resistance that certain fowls (as hens, pheasants) show to the reception of tuberculosis by ingestion of tuberculous matter, as the sputa of phthisical patients. Some of these fowls, which had

been fed for more than a year on phthisical sputa mixed with bread-crumbs, meal, etc., were shown to the Congress. They seemed to be perfectly healthy, and, on being killed, every one of them was found exempt from tuberculosis. The fowl is, however, not absolutely refractory to tuberculosis, as this disease has been known to prevail epidemically among hens.

MM. Strauss and Wurtz presented a valuable communication:

ON THE ACTION OF GASTRIC JUICE ON THE BACILLI OF TUBERCULOSIS.

It has been experimentally proved that the gastric juice has little power in destroying tubercle-bacilli, and the experiments of Chauveau, Gerlach, Klebs, Toussaint, etc., have shown that tuberculosis may be engendered by the ingestion of tuberculous products. If it were otherwise, there would, of course, be immunity from danger in eating tuberculous meat. Gastric juice *in vitro* only imperfectly destroys the spores of the bacilli, and its effect is very much lessened when dilated by food and drink.

Many other subjects were introduced and discussed during this long session, which lasted four days: such as "The Disinfection of Sputa" (regarded as very important by some of the speakers, patients being made to expectorate into strong sublimate solutions); "The Hygiene of Infants of Tuberculous Patients" (goat's milk is preferable to cow's, if for no other reason than that the goat is never tuberculous); "The Surgical Treatment of Certain Tuberculous Affections" (by curetting, the injection of iodoform in ether, etc.); "The Early Diagnosis of Tuberculosis in the Human Subject" (by inoculation of animals with suspected products, etc.).

The Congress adjourned, to meet two years hence under the presidency of M. Villemin.

Recent Literature.

Physical Development; or, the Laws Governing the Human System. By Nathan Allen, M.D., LL.D., member of the American Medical Association, etc. Boston: Lee & Shepard. New York: Charles T. Dillingham. 1888.

This volume of some 350 pages represents a considerable number of the previously published brochures of Dr. Allen, some of which the author tells us in his preface are out of print while the demand for them still continues. He has, therefore, in part rewritten them and added some new papers, introduced only the better part of some long articles, and so has virtually made a new book. Among the subjects treated are Physical Education in Amherst College. Remarks on Early Education and the Education of Girls. The Law of Longevity. Duties of Medical Men. Sanitary Science. Prevention of Crime. Changes in New England Population. Hereditary Influences. Prevention of Insanity. The Law of Human Increase. Heredity, a Source of Pauperism. Physical Degeneracy. College Sports. One of the longest chapters is the closing one, on the Normal Standard for Motherhood, in which the abnormalities connected with pregnancy, parturition, lactation and offspring are treated at some length, with suggestions of value to the medical as well as to the non-professional public, to which this book as a whole is apparently chiefly addressed.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 23, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: $5.00 *per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 Boylston Street, Boston, Mass.

GEGENBAUER ON CÆNOGENESIS.

A recent address by this distinguished anatomist calls our attention to a less pleasant aspect of the science of the day than that usually presented in the congratulatory speeches of anniversary orators. Together with the wonderful progress of the physical sciences, there has appeared, also, a vast amount of what we must call cheap, or rather, spurious science. Various causes combined to bring this about. Within the last thirty years the number of men devoted to science (not to count women and children) has increased almost beyond computation, and, inevitably, the quality has fallen far behind the quantity. The number of notable leaders in science, of men of absolutely first-class attainments and of universal reputation, has shown no great increase. To compare the followers of science to an army, we may say that within the last generation we have gained few more generals, but that trained soldiers, both officers and privates, have multiplied, and camp followers and "bummers" increased by geometrical progression. Among these last we include men of little general education, of no philosophical training, and, unfortunately, now and then, of no principle, who sometimes ignorantly, sometimes recklessly, teach as certain what is doubtful and as fact what is theory, or it may be guess-work. The fact that many of the consequences of the evolutionary hypothesis are or appear subversive of the established order alike in religion and society, make the doctrine more attractive to minds of a certain class. A natural result of this state of affairs is the prevalence of the most vague terms. What, for instance, is less definite than the term evolution itself, as used in popular science? To some it is synonymous with Darwinism, to others to progress by sudden transformations; to some with one system, to others with another; and although the systems agree in admitting change, they differ radically in the *modus operandi* they imply, and are quite impossible to reconcile one with another. We find, every day, in the writings of those of whom better should be expected,

the statement that such and such appearances are explained by evolution, without a hint as to the system the author believes in. As an instance of how diverse views are held on minor points, let us take the history of the mammalia. Many, perhaps most, believe that the higher orders come from the marsupials; Albrecht maintains that the promammalia were nearly allied to the cetacea, and Mivart suggests a double origin. Now, when we are told that some anomaly in the human body is easily explained by a glance at its ancestry, we certainly should be told also whether we are to look to the whales or to the kangaroos, to both or to neither.

Great honor is due to some of the leading anatomists of Germany for their courage in standing firm for true science in the place of guess-work. Virchow, Kölliker, Gegenbauer, and others are of this class. We have already alluded to the first two, and now we wish to call attention to the address of the last named at the recent meeting of the Anatomische Gesellschaft at Würzburg.

As is well known, one of the most striking generalizations that has been made on the basis of evolution is that in the development of the individual (ontogenesis) there are seen as transitory states what are permanent conditions in lower forms, and that thus, in ontogenesis, we have a recapitulation of the history of the development of the species (phylogenesis). The central idea of this hypothesis has met with much favor, and it needed no prophet to foretell that so attractive and so vague a theory would be greatly abused. Professor Gegenbauer points out that in *ontogenesis*, besides the transitory appearances of ancestral, or, presumably, ancestral forms (palingenesis), we must not overlook the appearance of others that can bear no such interpretation (cænogenesis). This, of course, is no new discovery, but, from the way the matter is sometimes treated, one would imagine that the stages of development of the embryo each and all represent in regular order the ancestry of the species. It is against this crude and incorrect teaching that Gegenbauer protests. We know, for instance, that in the embryo the cavity of the mouth is for a long time separated from that of the digestive canal, but there is no animal in which this is the permanent condition. There is no ancestral form with a neuro-enteric canal connecting the central nervous system and the intestinal tract.

Again, there are discrepancies in the order of appearance of structures. Thus, in the animal series, teeth are far older organs than lungs, but in the embryo we see the beginning of the lungs before that of the teeth. Many of these cænogenetic structures are distinctly teleological for the nourishment or protection of the individual embryo, as, for example, the amnion. Gegenbauer insists that it is most important for the proper study of the questions at issue to recognize distinctly which structures have any phylogenetic significance, and which have none. Nothing but error and confusion can result from regarding everything indiscriminately as representing earlier forms. If any of our readers have thought our remarks too severe, let them ponder the words of Gegenbauer himself: "As these cænogenetic conditions do not exist in adult organisms, they are assumed to exist in them, and so one goes on to construct fictitious conditions — nay, more, entirely fictitious organisms."

Having thus evolved, let us say, for example, a sham ancestor of a camel from one's inner consciousness, one compares it with a true camel, and draws conclusions from the points of resemblance or difference between the two species, one of which is wholly imaginary. One more quotation from Gegenbauer: "The uncritical use of the results of ontogenesis leaves the solid ground of experience and falls into baseless speculation. Pictures of the imagination take the place of real objects, and thus research is drawn aside from the only path by which the knowledge of the truth, and, consequently, lasting results can be reached." These are both bold and needed words, for which the great anatomist deserves the thanks of lovers of science. At the end of the address, Professor His expressed his gratification at what he had heard. He declared that it was disturbing to every branch of science to have its results drawn to the service of an engrossing theory before these results are yet firmly established. "Let research," said he, in conclusion, "go undisturbed on its way, and then no one need be anxious as to the final application of its results."

SACCHARINE CONSIDERED AS AN ANTISEPTIC OF THE DIGESTIVE PASSAGES.

ACCORDING to Constantine Paul,[1] saccharine is an excellent antiseptic for the digestive passages, not being toxic, and having an agreeable odor and savor.

In doses which do not exceed three or four grains, it causes no disturbance of nutrition; urea, phosphoric acid, the urinary salts, still continue normal in quantity. In Dr. Paul's experience with saccharine in diabetes it has seldom troubled the digestion, and he has seen patients who have taken it for more than five months without any evil results whatever. In other cases, however, it has seemed to arrest the digestive fermentations, causing pain in the stomach, diarrhœa, etc.

Dr. Paul insists especially on the antiseptic properties of saccharine. One part to two hundred prevents the ammoniacal fermentation of urine and arrests the development of the *bacterium terme* $\frac{1}{300}$; that of *staphylococcus pyogenes*, $\frac{1}{300}$, perceptibly antagonizes the growth of the streptococcus of puerperal fever.

Saccharine is, therefore, an excellent dentifrice or antiseptic of the mouth. A six per cent. alkaline solution is prepared: of this a teaspoonful is put in half a teacupful of water, which may be aromatized. You thus have an admirable antiseptic mouth-wash. A solution of this kind would be useful for washing out

[1] Acad. de Med., July 10, 1888.

the stomach in putrid dyspepsia and gastriectasis, or as a vesical injection in cystitis with ammoniacal urine.

According to a Paris letter in the *Therapeutic Gazette*, the use of saccharine has been prohibited in all substances intended for food, both in England and in France. It has been, so far, chiefly employed for adulterating purposes, champagne wines of German make, syrups, chocolates, etc., having been seized in which sugar was partly replaced by glucose seasoned with the new sweetening principle. The authorities have wisely decided that while saccharine may be very good for diabetics, or as an antiseptic medicament, its use in common articles of food is a rank adulteration that should not be tolerated. Its place is on the pharmacist's shelf, to be prescribed by the physician, and not on the breakfast-table.

MEDICAL NOTES.

— In view of a late unfortunate error whereby a physician called to see a woman ill in a police station, failed to recognize symptoms of narcotic poisoning and treated the case as one of alcoholic intoxication, with the result of the patient's death, a daily paper makes the suggestion that in every case of arrest for supposed drunkenness, an emetic be at once administered by the police authorities as soon as the patient is brought in. This addition of medical attendance to already multiform duties which so severely tax the capacities of many members of the force, seems hardly to promise success, though so far as the drunkard is concerned, such a course might conduce to temperance through the addition of one more to the hard things in the way of the transgressor. But the voice of the homœopath and the mind-curer would at once be raised in protest against so positive a treatment. We are regretfully obliged to conclude that despite "emergency lectures" and other kindred instruction to which the police have been introduced, the only really safe ground is for them to be ordered in all cases where unconscious persons come under their care, and the evidence of intoxication is not absolutely clear, to call for medical aid, not necessarily from the nearest "doctor" but from some one who has had experience in the sometimes not easy diagnosis of the different causes of unconsciousness.

— The *Detroit Free Press* thus lets open the floodgates upon a sweltering medical and pharmaceutical public:—

"'I want some consecrated lye,' he slowly announced as he entered the store. 'You mean concentrated lye,' suggested the druggist as he suppressed a smile. 'Well, maybe I do. It does nutmeg any difference. It's what I camphor, anyhow. What does it sulphur?' — 'Eighteen cents a can.' — 'Then you can give me a can.' — 'I never cinnamon who thought himself so witty as you do,' said the druggist in a gingerly manner, feeling called upon to do a little punning himself. 'Well, that's not bad, either,' replied the customer, with a syruptitious glance. 'I ammonia a novice at the business, though I've soda good many puns that other punsters reaped the credit of. However, I don't care a copperas far as I am concerned, though they ought to be handled without cloves till they wouldn't know what was the madder with them. Perhaps I shouldn't myrrh-myrrh. We had a pleasant time, and I shall caraway.' It was too much for the druggist. He had collapsed."

Miscellany.

MACTE LISTER TRIUMPHATOR!

A Moist-merry, Humid-hilarious Antiseptic Vade-mecum of Internal Surgery, for the Ambitious Modern Physician.

BY DR. RISORIUS SANTORINI. Translated by "FAMULUS."

All Rights Reserved. 1888.

INTRODUCTION.

There was a time, long years ago,
When all our colleagues flourished;
When Therapeutics, grand, sublime,
With tenderest care was nourished.
Before the bistoury and trocar
Had entered sick-room and boudoir,
In visceral disorders.

The doctor of those good old days,
In bonnet or in hat,
Gave man and woman, right and left,
Prescriptions "quantam sat."
His instruments, in scant array,
Scarce bulged the pocket where they lay,
Corrupt with filth and oxide.

He was withall a surgeon true,
See "quoniam — vir ingenio."
But timid operations few
Comprised him "ab initio."
He, forceps now and then applied,
With trembling midwife for a guide;
"*Three perineal sutures.*"

At times a fracture might occur,
And, rarely, dislocations;
But then, the shepherds cared for these,
As in all Christian nations.
The barber bled, and made the blisters;
The midwife filled and gave the clysters,
Leeched, poulticed and anointed.

So, to the doctor there remained
The visceral diseases;
But even these cases will not come
As often as he pleases.
But, called, the treatment he prepares,
By quarts and pounds and ample jars,
The malady to conquer.

Those were the days of golden gains
For each apothecary;
His friendship for the doctor grew
Like that of Tom for Jerry.
The ℞ and the prescriber too
Were lauded to the azure blue,
By the devout pill-vendor.

But, ah! for ideal therapy
Is now no occupation.
The world is changed; new modes prevail,
And always new vexation.
Internal Surgery claims the field
Where we the power were wont to wield,
And Lister is its champion.

The gathered wealth of roots and herbs
Is daily more neglected;
And only opium's alkaloid
As sedative respected.
Practitioners of code correct
Even find cocaine derelict
As local anæsthetic.

The Pharmacopœia is thrust aside,
A relic of past folly;
With "Seven Specifics" all is done;
It's true, but it's not jolly.
Iodoform is everywhere,
From end of toe to cranial hair,
With acid. sal., et cetera.

Dear Doctor, if you wish to perch
On topmost twig of science,
Practice but surgery, instead
Of drugs, upon your clients.
My counsel will earn many a fee;
Gird up your loins and follow me —
To operative glory.

CHAPTER I.

PLEURITIC EXUDATION.

With scarce a chance of variation
Death follows pleural exudation.—
But if it's *serous*, it may be
Removed by Nature perfectly;
Because absorption *may* take place,
And thus recovery end the case.

If the disease is still *acute*,
Blood-letting may exactly suit;
Followed by a depleting diet,
Emetics, purges, sweats and quiet.

But if at once we see the sign
Of quick increase, and course malign,
If apnœa the patient quails,
And visceral compensation fails,
This should suffice as ample warning
Not to delay till coming morning;
But tap the chest in time to save
The case from a prognosis grave.

But in a *moderate* exudation
No man would counsel exploration.
For it is clear that aspiration
Can never bring amelioration.
That's why our brethren in France
No longer trust unequal chance,
Who earlier counselled costal puncture,
But seldom now approach that juncture;
Because the death-rate's rapid rise
Disclosed its perils to their eyes.
Therefore, dear doctor, be not rash,
The trocar all your hopes may dash.

But if the exudation grows,
Or stationary aspect shows,
If the effusion should compress
The lung, and thus produce distress,—
With atrophy of parenchyma,—
Which oft induces emphysema,
With hypertrophia cardiæ,
And frequently bronchiectasie,
In short, if three weeks' medication
Have not produced amelioration;—
And if by means of Kœrner's method
The *status præsens* is not bettered;
Then you should puncture *instantly*
And set the lung from pressure free.

Is the effusion *purulent*,
It should be given instant vent,
For if you leave the suppuration
To be removed by cell-migration —
Because this now and then may happen —
And hesitate until cachexia
Appears with constant anorexia —
No, thank you. But be not afraid;
Seize boldly your aseptic blade;
Thoracoclasis must be done —
(Vide "Estlander," Vol. I.)
That is, the empyæma-sac
Must be incised from front to back.

If *decomposed* the liquid be,
It adds much to the gravity
Of the prognosis. This is very
Oft but a process secondary;
It follows on gangrena simplex,
E. g., from abscess near the apex;
Cases of bronchiectasie,
As part of their pathology.

Sometimes indeed to our surprise,
A *putrid focus* hidden lies.
This to relieve you should endeavor;
But don't transfix the spleen or liver.
Resound the praise of our vocation!—
Some *have survived* this operation.
. . . . . .
The case pursues a course most tragic
If the effusion's hæmorrhagic;
Although this oft is secondary
To some disease preliminary,
Like cancer or tuberculosis,
Scorbutus, also trichinosis,
Alcoholismus, Bright's, et cetera.

We cannot hope by operation
To gain the least amelioration;
Because the effusion, though reduced,
Is instantly again produced.

We should advise *thoracentesis*
Only when fluid quick increases
Without a known diathesis.
Therefore, if by aspiration
We find a sanguine exudation,
Even if the fluid be *tinged* but bloody,
The Anamnesia we would study;—
But therapy can naught avail.

Conclusio: When the fluid content
Within the chest is subsequent

To a primary process causal
Which *a priori*, is lethal.
All hope is vain, we must agree,
From pulmonary surgery.

But empyema, be it noted,
Falls not within the rule here quoted.

CHAPTER II.

PULMONARY SURGERY.

Of all the viscera, none we see
Changed by disease more frequently
Than is the lung, that grand creation,
On which depends the respiration.
Even if the ambient atmosphere
Were from disease-bacilli clear,
Which once was true in each large town,
As in tradition handed down,
Where Public Sanitation wages
To-day, as in the Middle Ages,
War 'gainst disease in all gradation
From sausage to small-pox-invasion,
Till, without fear of contradiction,
Or being accused of speaking fiction,
We see the prospect indicated,
Phthisis will be exterminated;
Still there remains to taunt ambition
Many a morbid lung-condition,
Which, in the parenchyma seated,
With zeal and vigor must be treated.

But here, again, we see with anguish
That although science does not languish,
But probes the etiology —
We nothing gain in therapy.
For with resinæ podophylli
We fail to drive out the bacilli
Which swarm with reproductive issue
All through the pulmonary tissue.
. . . . . .
At length, when we so long have waited
To see our science vindicated,
Pulmonary Surgery takes its rise!
Let loud hosannas reach the skies!

(a) *Parenchymatous Injection of the Lung.*

What theory have we to guide us
In understanding what 's inside us?
Does Nature act with clear intention?
Reveal design? Display invention?
What could on Nature else prevail
To guard our lungs with coat of mail?
Ah! friend, for Lister's army brave
There is no barrier but the grave.

Deep in our vitals they intrude
And saturate with certitude
The foci where the germs locate
With iodoform and sublimate.
That is, they *speculate*, they *hope*
Thus with diseases grave to cope;
That they may check the irritation
And modify the inflammation,
And by repeated deep injection
May hinder general infection.

Yes, even in tuberculous centres
The aspiration-needle enters.

And, as this therapeutic feature
Is still advanced by each new teacher,
We' ll lock each bacillary matrix
Within a layer of cicatrix.
. . . . . .
Next comes a matter of great gravity,
The sterilization of the cavity;
But — *nota bene* — the physician
Must first locate it with precision,
Determine if the content 's cheesy —
A task which is not always easy.
. . . . . .
In Dorpat dwelt Herr Dr. Koch;
Who used potass. iod. injection
"Almost without febrile reaction"
(Take care; this was on animals);
And found the adjacent lymph-canals
Closed by cicatrix. Yes, on paper
This seems a very proper caper;
But such results within the lung
Are not so easy made as sung.
That lung must in a bear's chest grow
To kindly stop *in statuo quo*
When filled with iodine injection.

"Rational" treatment now is able
On grave disease to turn the table.
Each case of pulmonary trouble
(Especially if it be not double)
Must be attacked by surgery,
If brilliant cures we wish to see.

Mosler brought bronchiectasie
Within thoracic surgery,
And sought to prove to every sceptic
The need of treatment antiseptic.
He made an opening in the lesion,
And aspirated the secretion;
Left a large canula within
For irrigation, p. r. n.

With Koch's and Mosler's theories gifted
(It 's always so), our colleagues shifted.
The eager group which sees perfection
In each new method tried injection.
They thought all cases thus to treat,
Unmindful of the cause or seat,
Not only in tuberculosis,
Putrid bronchitis, lung-necrosis,
Ecchinococcus (several cases),
Infarcts and multiple abscesses.
Recent disease, as well as chronic,
Was treated by this mode Teutonic.
This not exactly a *meme chose* is
In gangrene or tuberculosis.

Argentum nit. and iodine,
Carbolic acid. salicine,
Potassii permanganicum,
With extract queucus fluidum,
Were pumped without a qualm or tremor
Through the pulmonic parenchyma.

Pneumonia due to germ-infection
Lepine then treated by injection,
Where still the lung was hepatized
With hyd. bi-chloride vaporized.
Whereby, not only — thank the Lord! —
The temperature "at once was lowered,"

But this subdued the inflammation,
And — presto — stopped the crepitation!
Then vivat, crescat, floreat
Renowned corrosive sublimate!
And may the great name of Lepine
Be emblazoned on Apollo's shrine!

But I, my friend, hold strong conviction
Against Lepine's heroic prescription.
The lung, with sixty hours' duration
Of sharp and vivid inflammation
Cannot at once resume its function,
Even by mercurial inunction!
Lepine, with zeal and tact ambitious,
Has taught a doctrine most pernicious!

This factum note: — Against injection
You should afford the lung protection
In phthisis and pneumonia.
Only in bronchiectasie
With well-determined cavity;
When even profuse expectoration
Does not reduce the exudation;
So that gangrene, thrombosis, dropsy,
Suggest the patient's near autopsy,
You should with promptness operate,
And flush with sodium carbolate.

(b) *Opening and Draining of Pulmonary Cavities.*

In diagnosis, great vexation
Pertains to bronchial dilatation.
In size and seat it's most erratic,
Presents no features symptomatic;
May be in front, or far posterior,
In apex, or in lobe inferior;
Sometimes it's large, with capsule dural;
It may be deep, may be sub-pleural;
Sometimes a single tube's dilated;
But usually it's disseminated,
And wakes a crepitation-chorus,
Till we scarce know what is before us.
In short, you'll find it, I may state,
Quite hard to diagnosticate.

But if kind fate should grant to you
To localize a focus true
By tympanitic resonance,
Our therapy claims no advance.
Still if the use of Abbé's prism
Reveals no septic organism,
Then operate both deep and wide —
The holy Mosler be your guide.

He cured a follower of St. Dominic
At Greifswald, [vide Hueter's Clinic]; —
Too freely quoted it can't be,
This famous case of bronchiectasie.
Eh? — cured? — How can you make the query?
Such a suggestion makes me weary
Three months and more of time went past
Before the patient breathed his last!
In the report of the obduction —
Perhaps through wilful misconstruction —
We find, as total diagnosis,
The single word "tuberculosis!"

Therefore — bacilli being detected,
Trocar and drain must be rejected!
In case of bronchial dilatation
'T will surely prove an aggravation.

Renounce the knife — bold measures cease,
And let the patient die in peace.

In abscess of the lung, however,
To free the pus you should endeavor.
But if gangrene is on the docket,
Then put your lancet in your pocket.

Here it's important you should try
To trace the etiology!
If it is primary, make no parley; —
The case has else but one finale; —
Provide immediate path of drain;
Let not a drop of pus remain.

But if the gangrene is a sequel
E. g., of abscess or its equal,
Pneumonia interstitialis,
Or infarct hæmorrhag. centralis,
Waste no more time in medication,
But follow Fenger's innovation.

You may in this be justified
By previous puncture though the side: —
Although the smell is quite sufficient
To indicate what ails the patient; —
Added to this — without cessation
A grayish-red expectoration: —
Quickly the ribs must be resected,
The cavity throughout inspected —
Then by the aid of Paquelin's cautery,
Proceed to carbonize the cavity;
And follow out each wandering sinus
Whate'er its nature, great or minus;
Then as the climax of devotion
Wash out with salicylic lotion,
Insufflate well with iodoform,
The enemy of every germ;
Drain-tubes a couple, gauze and peat
Bandage, and India-rubber sheet. —
Then should the patient live or perish,
You've none but pleasant thoughts to cherish.
You've followed Lister's full direction,
And can repose in his protection.

(To be continued.)

LINEÆ ALBICANTES IN TYPHOID FEVER.

THE *Lancet* remarks that sometimes atrophic lines so common after distension of the skin appear without any obvious cause of stretching. Manouvriez and Bouchard have recorded such cases occurring in the course of convalescence from typhoid fever. Troisier has given an interesting account of this condition in the *Bulletin de la Société Médicale des Hôpitaux*, No. 12. These lines have been noticed, especially in children and young adults. Bouchard considered that they were due to stretching resulting from rapid growth after the subsidence of the fever. Troisier and Menetrier have noted that the elastic tissues of the skin are less thick at the level of the "atrophic" area, but they failed to find any real evidence of wasting of tissue; the elastic fibres were simply torn through and curled up at their broken ends. M. Bucquoy said that in boys the whitish lines have no special distribution, but in girls the breasts and the iliac crests appear to be chosen sites. M. Barié referred to a case in a girl aged seventeen, in whom the lines were situated over the tibio-tarsal articulation on each side.

MERCURIC CHANGED TO MERCUROUS CHLORIDE.

DR. SAMUEL KENNEDY communicates to the *Pharmaceutic Record* the results of his experiments with bichloride of mercury in solution.

He found by repeated testing that compound syrup of sarsaparilla reduces mercuric to mercurous chloride. If a little common salt is added to the solution, the buff-colored precipitate of calomel does not take place for at least two or three weeks. He advises to add to prescriptions in which corrosive sublimate enters as an ingredient, an amount of common salt equal to the weight of the corrosive sublimate.

Correspondence.

DINNER TO FOREIGN GUESTS OF THE CONGRESS OF PHYSICIANS AND SURGEONS.

WASHINGTON, August 21, 1888.

MR. EDITOR, — Some complaints having reached the committee in regard to the distribution of invitations to the dinner to be given to the foreign guests of the Congress of Physicians and Surgeons, to be held in this city next month, I must beg the use of your columns to say that this distribution was in my hands.

The council of the Congress having expressed themselves as averse to any elaborate entertainment on the part of the Congress, it may be said, in the first place, that this dinner is *unofficial*, and is in the hands of the *members* of the committee, and not of the committee. As it was necessary, after the matter was decided upon, to act quickly in order that proper invitations might be sent to Europe and answered in time, it was not possible to arrange this distribution so methodically as might have been done had the time been longer. It was intended that every member of the Congress, that is, every member of any of the constituent associations, should have an opportunity to subscribe.

Some circulars were sent directly by me, and some of them by such representatives of the associations as I could most readily get at. It is possible that there may have been some accidental omissions; and it is more than possible that at this season, when so many gentlemen are absent from home, some invitations may have gone astray. Another possibility, which we know to have been in some cases an absolute fact, is that they have been placed in the waste-paper basket.

This note is intended as an invitation to every member of all the associations composing the Congress of American Physicians and Surgeons, who wishes to do so, to send his subscription of twenty dollars to Dr. S. C. Busey, 1545 I St., N. W., Washington, D. C., for a dinner to be given at Willard's Hotel in this city, on Monday, September 17th, at 7.30 P. M.

I am, very respectfully,
ROBERT T. EDES, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 11, 1888.

Cities.	Estimated Population for 1888.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Northampton	13,419	6	2	16.66	—	16.66	—	—

Deaths reported 2,531: under five years of age 1,291; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 874, consumption 253, acute lung diseases 119, diarrhœal diseases 628, diphtheria and croup 76, typhoid fever 66, whooping-cough 38, scarlet fever 20, measles 13, malarial fever 11, cerebro-spinal meningitis 10, puerperal fever eight, small-pox two, erysipelas two. From whooping-cough, New York 15, Washington eight, Philadelphia and Brooklyn four each, Boston, Pittsburgh and Cambridge two each, Fall River one. From scarlet fever New York 14, Philadelphia four, Brooklyn and Nashville one each. From measles New York 11, Pittsburgh and Lawrence one each. From malarial fevers New York six, Brooklyn three, Nashville and Charleston one each. From cerebro-spinal meningitis, Washington three, New York, Nashville and Lynn two each, Somerville one. From puerperal fever Pittsburgh four, Fall River two, Boston and Washington one each. From small-pox, Philadelphia two. From erysipelas, New York two.

The meteorological record for the week ending August 11, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, Aug. 11, 1888.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.		State of Weather.[1]		Rainfall.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE TWO WEEKS ENDING AUGUST 18, 1888.

WHITAKER, H. W., passed assistant surgeon. Detached from the "Mohican" proceed home and await orders.

FERREER, N. M., surgeon. Detached from the "Franklin" and to the Naval Hospital, Norfolk, Va.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING AUGUST 13, 1888.

PURVIANCE, GEORGE, surgeon. Granted leave of absence for thirty days. August 13, 1888.

SAWTELLE, H. W., surgeon. Detailed as member of Board to select site for quarantine station at San Diego, Cal. August 6, 1888.

GOLDSBOROUGH, C. B., surgeon. Granted leave of absence for thirty days. August 10, 1888.

GUITERAS, JOHN, passed assistant surgeon. To proceed to Sanford and Jacksonville, Fla., and Way Cross and DuPont, Ga., on special duty. August 1, 6, 9, 10, 1888.

BANKS, C. E., passed assistant surgeon. Granted leave of absence for four days. August 6, 9, 1888.

PECKHAM, C. T., passed assistant surgeon. Granted leave of absence for thirty days. August 10, 1888.

URQUHART, F. M., passed assistant surgeon. To proceed to Way Cross, Ga., on special duty. August 9, 1888.

GLENNAN, A. H., passed assistant surgeon. Detailed as member of Board to select site for quarantine station at Port Townsend, Wash. August 6, 1888.

WASDIN, EUGENE, passed assistant surgeon. Detailed as member of Board to select site for quarantine station at Key West, Fla. August 6, 1888.

WILLIAMS, L. L., passed assistant surgeon. Granted leave of absence for fifteen days on account of sickness. August 10, 1888.

STONER, J. B., assistant surgeon. To proceed to Norfolk, Va., for temporary duty. August 9, 1888.

SOCIETY NOTICE.

AMERICAN DERMATOLOGICAL ASSOCIATION.— Programme of the Twelfth Annual Meeting to be held at Willard's Hotel, Washington, D. C., September 18, 19, and 20, 1888. Officers for 1888. President, Dr. I. E. Atkinson, of Baltimore. Vice-President, Dr. P. A. Morrow, of New York. Secretary and Treasurer, Dr. G. H. Tilden, of Boston.

First Day. Tuesday, September 18th.— Business Meeting (with closed doors), at 9.30 A. M. Morning Session at 10.30 A. M. Address by the President, Dr. I. E. Atkinson. (1) The Electrolytic Decomposition of Organic Tissues, Dr. G. H. Rohe. (2) The Value of Salicylic Acid in Dermatology, Dr. Heitzmann. (3) Hereditary Dermatoses, Dr. J. C. White. Adjournment at 1.30 P. M. Afternoon Session at 3.30 P. M. (4) A Report of Four Cases of Dermatitis Herpetiformis, Dr. J. E. Graham. (5) Dermatitis Herpetiformis, with Notes of Three Cases, Dr. H. W. Stelwagon. (6) Personal Observations on Skin Diseases in the Negro, Dr. R. B. Morison. (7) Note of a Case of Filaria Medinensis, Dr. A. Van Harlingen. Adjournment at 5.30 P. M.

Second Day. Wednesday, September 19th.— Business Meeting (with closed doors), at 9.30 A. M. Morning Session at 10.30 A. M. Report of Committee on Statistics: Report of Committee on Nomenclature. (8) So-Called Acne Anthracoide Iodopotassique, Dr. R. W. Taylor. (9) Note Relative to the Vegetative Lesions Induced by Ingestion of some of the Iodine Compounds, Dr. J. N. Hyde. (10) Notes on Some Unusual Cases of Skin Disease, Dr. W. A. Hardaway. (11) A Contribution to the Clinical History of Alopecia Areata, Dr. A. Van Harlingen. Adjournment at 1.30 P. M. Afternoon Session at 3.30 P. M. (12) The Non-Identity of Lichen Planus and Lichen Ruber, Dr. G. H. Fox. (13) The Question of Relationship between Lichen Ruber (Hebra) and Lichen Planus (Wilson), Dr. A. R. Robinson. (14) Multiple Pigmentary Sarcoma, Dr. E. B. Bronson. (15) Dermatitis Plantaris and Palmaris, Dr. L. Duncan Bulkley. Adjournment at 5.30 P. M.

Third Day. Thursday, September 20th.— Morning Session at 10 A. M. (16) Raynaud's Disease and Symmetrical Gangrene in late Syphilis, Dr. R. W. Taylor. (17) The Relation of Framboesia to Syphilis and Tuberculosis of the Skin, with Report of a Case, Dr. P. A. Morrow. (18) Kraurosis of the Vulva (Breisky), Dr. C. Heitzmann. (19) Molluscum Contagiosum, a Clinical Report, Dr. H. W. Stelwagon. Retirement of old, and induction of newly-elected officers. Adjournment at 1 P. M.

OBSERVATIONS ON THE SURGICAL TREATMENT OF MALIGNANT GROWTHS.[1]

BY MAURICE H. RICHARDSON, M.D., OF BOSTON.

At the annual meeting of this Society in June, 1886, Dr. Hodges, in his admirable address, made the following statement: "Therapeutics, when not guided by an intelligent and definite purpose, are superfluous and meddlesome. Surgical operations which, from the outset, it is known cannot be completed, and into which every surgeon remembers with regret that he has been drawn by some vague expectation of benefit — the infiltrating epitheliomata, the adherent and fatally located tumors, the malignant growths sure to return, the limbs crushed in railroad accidents from which he has not withheld his hand — have certainly contributed nothing to the self-satisfaction of the operator, or helped to advance even the purely mechanical part of surgery. . . . The operation for cancer of the breast was as habitual as it is now exceptional — or, at least, as it soon will be."

He refers to the *Lancet*, March 21, 1885, p. 527, and January 9, 1886, p. 72. In a foot-note quoting from Vernueil (*N. Y. Med. Record*, January 9, 1886, p. 56): "Of one hundred possible operations, twenty are imperatively necessary, twenty are absolutely inadmissible, and the remaining sixty may be performed or not, according to circumstances, and surgeons may and do err in each of these classes of cases."

Such an expression of opinion from so eminent an authority in surgery as Dr. Hodges deserves the greatest respect, and carries great weight. I certainly agree with him in most of the opinions quoted above. No surgeon can object to the opinion that operations should not be undertaken where the malignant growth cannot be completely removed, if this can be known beforehand, unless it is done for other reasons than the hope of a permanent cure, or adding materially to the duration of life.

To the second statement — that the operation for cancer of the breast is now exceptional or soon will be — I take exception, and I have ventured to present my views on this subject, and to give my reasons, in the following paper, why I believe that the excision of tumors of the breast, as well as of other parts of the body, will become more frequent, as well as more successful.

The work necessary for the preparation of a paper based upon the experience of the Massachusetts General Hospital is very great indeed. Last year, I began the work of collecting all the cases of malignant disease treated in the Hospital by excision from November 1, 1877, to January 1, 1887. Thus far I have collected only the tumors located in the easily accessible parts of the body, and I shall consider in this paper only growths located on the face, lips, lids, scalp, ear, and tongue, the neck and body, the breast, the upper and lower extremities, and the external male and female genitals.

I cannot state my belief as to the best treatment of malignant growths better than by quoting from the authority referred to by Dr. Hodges in his paper (*Lancet*, January 9, 1886, p. 72, editorial): "A great risk and a severe operation are only justifiable when the advantage is also great. When, for example, an operation promises complete cure or long immunity from an otherwise certainly fatal malady, it is obviously right to undertake it, even if it be severe and dangerous. This is a somewhat self-evident proposition, and yet one of its applications to practice is often lost sight of. Experience has fully shown that, other things being equal, the success of excision of malignant growths is largely dependent upon the period at which they are performed. As, therefore, an early operation for cancer offers a far greater prospect of long immunity from recurrence than a later one, a wide and more severe operation is justified in the earlier, rather than in the later stage. The contrary view is sometimes acted upon, even when not actually stated. Excisions of limited extent are often practised when malignant tumors are small, and because they are small and of recent origin, while in tumors of greater age and more extensive growth more formidable operations are readily undertaken, in spite of the small prospect of success they hold out. The converse should be the rule. When the surgeon has to do with a case in which a free excision holds out a strong hope of long immunity, or even a cure, a very thorough operation should be performed, even although it cause some deformity or mutilation, or expose the patient's life to danger. The great advantage to be expected from such an operation justifies the greater severity and the extra risk of such a procedure. Where the object aimed at is the removal of a malignant tumor, with a view of interrupting for a time or stopping forever its growth, the principle should be kept in view, and, if it were fully carried out in the early operations, we believe the practice would be attended with most favorable results."

Speaking of operations of great severity, where it is merely a question of prolonging life: "In all the isolated brilliant achievements of surgeons in this region of practice, it is doubtful whether some of these operations have resulted in adding to the sum total of human life; the prolongation of a life here and there does not compensate for the cutting short of that of many others."

I believe that the immediate future will see a great increase in the number of these operations, and very much greater success will follow them by the recognition, on the part of the general practitioner, of the vital importance of early diagnosis and excision of all growths situated in those parts of the body especially liable to malignant disease, and by the adoption on the part of the operator of the principle quoted, that it is in the early stage of the disease that the most radical operation should be done.

It is hardly necessary for me to call the attention of members of the Society to the dreadful condition of body and mind to which this fearful disease sooner or later reduces the unfortunate patient. Every physician knows that malignant disease, especially certain forms of carcinoma, is a terrible thing. If left to itself there is a period of life, quite definitely shown by statistical tables, during which the life of the patient is one of dreadful suffering, and he may become an object of loathing to himself and his friends. It is a mercy if this period is shortened by intercurrent disease or by the early invasion of the internal organs.

From a great mass of statistics, we can easily find the average duration of life in different forms of malignant disease where no operation has been done. We

[1] Read before the Massachusetts Medical Society, June 13, 1888, and recommended for publication by the Society.

can ascertain in the same way the duration of life in all the great classes of malignant disease where an operation for relief or cure has been done, and it must be acknowledged that in most forms the prolongation of life and the alleviation of suffering do not present a very favorable outlook. But, nevertheless, it does not seem to me that we are justified, in the face of these statistics, in saying that all attempts at cure or relief should, therefore, be abandoned. Probably every physician in this room has had cases, or knows of cases, in which an operation for the cure of cancer has been perfectly and permanently successful. If we can show that there is even a small percentage of complete recoveries, are we not justified, and is it not our duty, to operate in all cases where there is no definite contraindication, as shown below? It is certain that in many cases life is prolonged for years. It is no doubt true, also, that in a certain number of cases life is shortened; but, if we analyze such cases, we shall find, I think, that in the majority of them the disease was attended by such conditions as would, in my opinion, now render an operation unadvisable.

I would say here, once for all, that cases evidently incurable are not considered at all in this paper. Even in hopeless cases, no one will deny, I think, that operations are sometimes demanded for the relief of pain or the removal of an offensive mass.

It is generally admitted that malignant disease is a local, not a constitutional affection. We must look, then, for the cause of failure in the operation itself, provided we can show that in a given case there was no invasions of distant organs by the disease which was overlooked. The points to be considered in the following analysis of cases are, first, the thoroughness of the excision, and second, the evidence by which we can decide that an operation is inadmissible.

The cause of the ill-success hitherto met with in these operations is: (1) in early and favorable cases the excision is not thorough; (2) sufficient attention is not given to the existence of glandular infection and metastasis of the internal organs as contraindications.

It is the imperative duty of every surgeon and every practitioner of medicine to investigate at once every new growth which comes under his observation, with a view to perform the most radical excision as soon as its malignancy has become established, provided, of course, the disease can be thoroughly removed, and provided there are no contraindications either in the disease itself or in the general condition of the patient. The most favorable time for operation is the very earliest possible after its discovery, and *then* is the time when a thorough removal promises the best chance for recovery. I am perfectly aware that all these remarks are truisms, but, nevertheless, it seems to me worth while to emphasize them again. Nothing is more common in the experience of every surgeon than to meet with cases of inoperable malignant disease which have been treated for a long time as benign by local applications, constitutional remedies and other methods, while the favorable opportunity for surgical interference has been lost. All cases, for instance, of ulceration of the lip after the age of thirty; all slowly growing tumors of the breast after the age of thirty; the rapidly growing tumors of childhood and youth; in fact, all rapidly growing tumors of all times of life are of sufficient gravity to make it the imperative duty of the attending physician to take measures to ascertain their nature. It is not right to allow a crust or ulceration of the lip to grow unchecked, or to allow a tumor of the breast to increase until the axillary glands become involved, in the hope that there is nothing malignant in these cases, when we know that by far the greater number of them, after the age of thirty, are malignant, and that a most fearful death awaits the patient, in the course of a short time, if something is not done to prevent it. It is of the greatest importance, then, to recognize at the earliest possible moment the existence and nature of a new growth, no matter how trivial, in any part of the body which is known to be the common seat of malignant disease. A lady of forty-five consults the physician for a small lump which she has discovered in her breast. She is very nervous and much excited, and fears that she has a cancer of the breast. It is the natural wish of the physician to assure her that it is probably nothing, that it has always existed, and will never amount to anything. But do we not by such advice allow the opportune moment to escape? Is not this the time when of all times an operation should be advised and done? The lady presents herself again, perhaps, for examination in the course of six months or a year. Resting upon the assurance of the physician, nothing has been done; her mind has been at rest, and the gradual enlargement of the growth has excited no fresh apprehension. She is again examined and the axillary glands are found involved. An operation is now advised and performed. The focus of infection which at first was limited to the breast, and which might have been removed most thoroughly, has already extended to numerous points in the axilla. A much more radical operation has become necessary, and her chance for recovery has been diminished. The same experience is constantly met with in ulcerations of the lip. I would, therefore, emphasize most strongly the importance on the part of every physician of early recognition of the nature of all new growths.

When the malignancy of the growth has been established by microscopic examination, and when by the most searching physical examination no extension can be found to exist in the thorax or abdomen, and when the lymph-glands are unaffected, or if involved they are within reach and admit of complete excision, then the operation should be undertaken. But even then the patient should be informed of the serious nature of the disease and the probability of recurrence, before excision should be performed. It is not right to subject any patient to an operation with the assurance that there is no danger of return. He has a right to know the facts before submitting to the necessary suffering, and incurring risk of immediate death. In this way the surgeon and his art will be protected from the criticism, too often true, that harm has been done instead of good, and that life has been shortened rather than prolonged. Such criticisms, no doubt often undeserved and unjust, are very common among the laity, and many have come to me among the responses to my letters. By careful attention to these suggestions, in every case, I am convinced that not only will many fatal results be avoided, but in the event of recurrence the friends and the patient himself will have no cause to complain.

The operation of excision should never be undertaken unless it is certain that all the growth can be removed, — that is, as an operation for cure. When

it has been decided that complete excision is possible, or that it is not impossible, then the growth should be removed with the knife in such a manner as to take with the tumor a broad margin of skin and a deep layer of healthy subjacent tissue, regardless of deformity or mutilation.

The existence of affected lymph-glands, while it is almost a contraindication to the performance of an operation, does not necessarily remove all chances of cure. When they are present they should be removed in the most thorough manner as far as they can be felt, with the surrounding tissues, and with all the parts between them and the tumor through which the lymph vessels are known to run. I have met with many cases, especially in cancer of the breast, where there has been immunity from the disease for several years, and where the reappearance has taken place in the breast scar rather than in the axilla, after the most thorough dissection of that space.

I have no doubt that it is impracticable to perform as thorough excision as I have recommended, especially in cases of mutilation of the features, yet I am fully convinced that such mutilations in the first operation, — in epitheliomata of the lip and lid for example, — would prevent in a great many cases the horrid deformities which make their appearance in the later stages of the disease.

From November 1, 1877 to January 1, 1887, eight hundred and thirty-three cases of new growths were treated at the Massachusetts General Hospital by excision. It is very probable that some of these were not malignant, but by far the greater number were. They embrace all varieties of malignancy, all ages, and all occupations. Of these eight hundred and thirty-three cases I have recent information in four hundred and ninety-eight. Of the four hundred and ninety-eight, two hundred and fifty-one are living and two hundred and forty-seven are dead.

Of those operated on previous to 1881, there are now living, 38.2%; dead, 61.8%.

Operated upon in	1881	Living,	52.8%	Dead,	47.2%
"	1882	"	45.6	"	54.4
"	1883	"	49.2	"	50.8
"	1884	"	59.4	"	40.6
"	1885	"	61.	"	39.
"	1886	"	71.4	"	28.6

I have not included in these returns those cases where I have obtained information not accompanied with that of their present condition. There are many cases where the patient was incurable and where no second operation was done, which would increase the death side of the table very materially.

Taken as a whole these cases present very hopeful results and encourage, I think, the performance of excision as a general rule. If the present practice of more radical excision had been done in all these cases, and if fewer attempts had been made in the now-considered hopeless cases, I have no doubt the showing would have been much better than it is.

First in importance and frequency come Tumors of the Breast, with 274 operations. I have received 163 replies. Of the 163, 68 are living and 95 dead.

Next comes Epitheliomata of Head, Neck and Face, with 114 cases, from whom I have received 67 replies, with 34 living and 33 dead.

Tumors of the Extremities, all varieties. 89 cases; 56 replies, 37 living and 19 dead.

Cancer of Lip. 75 cases (not included in Epitheliomata), with 51 replies, 26 living and 25 dead.

Tumors of the Jaws. 40 cases; 20 replies, 11 living and nine dead. (Not including Epulis.)

Epulis. 20 cases; 11 answers, 10 living and 1 dead.

Penis. 22 cases; 10 answers, 6 living and 4 dead.

Female Genitals. 14 cases; 3 answers, 2 living and 1 dead.

Tongue. 20 cases; 13 answers, 11 dead, 2 living.

Palate. 6 cases; 6 replies, 4 living and 2 dead.

Tonsil. 1 case, living.

Parotid. 11 cases; 5 replies, all living and well.

Melanotic Sarcomata. 10 cases; 8 replies, 1 living and 7 dead. The only living case was undoubtedly a melanotic sarcoma shown by the microscope.

Lymphosarcomata. Besides those cases included in the parts already given, 4 cases; 3 replies, all dead.

Excision of Tumors of the Testicle. 15 cases; replies 9, living 2 and dead 7. The 2 living cases were sarcoma and tuberculosis.

It must be borne in mind that there are quite a number of cases included in these lists which are probably not malignant. It is very unfortunate that there has been no microscopic examination in so many of the older cases. Death from a tumor or recurrence is sufficient evidence, however, of the malignancy of it. It has been impossible for me to go over all the cases and make the proper eliminations, except in the tumors of the breast, so that the figures and percentages are not as yet correct. They are sufficiently accurate, I think, for me to draw certain conclusions at this time. In a later paper I hope to be able to present the evidence in a more satisfactory form.

First in malignancy and fatality come the few cases of Lymphosarcomata,— all being now dead that have been heard from. Next come the Melanotic Sarcomata, with 7 dead out of 8. 87.5%.

Cancer of the Tongue, 84.6% dead.
Tumors of the Testicle, 77% dead.
Tumors of the Breast, 58% dead.
Epitheliomata of Face, etc., 49.2% dead.
Cancer of the Lip, 49% dead.
Tumors of the Jaws, 45% dead.
Cancer of the Penis, 40% dead.
Tumors of the Extremities, 34% dead.
Female Genitals, 33.3% dead.
Tumors of the Palate, 33.3% dead.
Tonsil and Parotid, all living.

While I am perfectly aware that these figures are not entirely reliable and accurate, as showing the percentage of recurrence and death after operation for malignant disease, and are open to criticism because the variety of growth is not given in all cases, yet in a general way they show the comparative malignancy of the various classes and situations, and enable me to emphasize certain facts to which I wish to call attention. We can say, for example, that operations undertaken for the cure of cancer of the tongue, as performed at the hospital during the past twelve years, offer very little chance of success, and the same may be said of the lympho- and melanotic-sarcomata. Tumors of the testicle and jaws also present a fearful mortality during that period. On the other hand, tumors of the palate, of the extremities (especially where amputation has been done), and even cancer of the lip and epitheliomta of the face, present much more favorable showings.

There is left the middle and much more important class of tumors of the breast, where the present living

percentage of forty-two per cent. is encouraging enough to justify renewed efforts in that direction.

Lymphosarcomata.— The results in these operations are too few to base much upon them. I do not believe, however, that excision of a large number of these glands in the neck will long continue to be good practice. I have done the operation several times, and have removed at one operation forty-five glands from the neck, and within a month as many more from the same boy. I do not believe that it is possible to effect a permanent cure, unless it can be reasonably certain that there are but one or two glands affected, and those within easy reach. I would apply the same general rule to these glands that I would to the secondary infiltration of the axillary glands in carcinoma of the breast, or to that following malignant disease of the extremities, namely, that no operation is justifiable where the glands are beyond easy reach. That is to say, when the infected gland is above the clavicle in breast and arm cases, or behind it in neck cases, or above Poupart's ligament behind the peritoneum in cancer of the genitals or of the lower extremity. In a case of lymphosarcoma, where but one gland is involved, it seems to me that operation is imperative; but in cases where a great mass of glands fills the neck and axilla, I believe that nothing can be expected beyond a possible prolongation of life and that is very uncertain.

Melanotic Sarcomata.— The mortality is extremely discouraging in this class of tumor. Most of the cases have affected the lower extremity. In these cases I believe that an early realization of the nature of the case, and the most thorough application of the most radical methods of excision will be followed by more favorable results. Such a case, a melanotic-sarcoma of the foot for example, if discovered before any glandular infiltration has taken place, demands amputation at once. The tendency of this disease to glandular complications and internal metastases will always make the failures large. In this, as in other forms of malignant disease to be considered, the ideal operation cannot be performed because of the very natural objection on the part of the patient to a sacrifice so out of proportion to the apparent necessities of the case. Yet it seems to me that the facts demand that the most radical measures be selected to meet the dangers of early internal infection in the melanotic sarcomata.

Cancer of the Tongue. — This is equally discouraging. Of the two cases now living out of a possible thirteen, one was probably not malignant, and the other so small that a wide margin of healthy tissue was left.

No attempt at removal of the tongue is justifiable, judging from these few cases alone, unless the operation is so radical as to leave a wide margin of unaffected parts. I believe that total excision is the only justifiable practice where the tumor is of any extent. The rapidity of growth of this disease makes it very important that it should be recognized early. It should then be most thoroughly removed, even sacrificing the whole organ if necessary, but should not be done, as it seems to me, where there is the additional complication of invaded cervical glands. That adds, I think, the deciding element.

Of the eleven cases heard from, nine are dead. One of the living should be excluded. The other living case was operated upon in 1884, and the tumor was very small and easily excised. One of the deaths followed the operation, one occurred at the end of three months, one at four, one at five, one at six, one at twelve, one at fourteen, two at twenty, and one uncertain. The average duration of life was ten and a half months. It can hardly be said that life has been prolonged in these cases to any considerable degree, certainly not enough to justify the operation.

In such cases as these it seems to me that true conservatism demands that very few of them be touched, but when an operation is done it should be of the most thorough and formidable character. Removal by any other means than the knife, or, the growth being located near the tip of the tongue, the écraseur or the ligature, is not to be thought of for the purpose of cure.

(To be continued.)

REPORT OF CASES CONFINED AT THE BOSTON LYING-IN HOSPITAL DURING THE THREE MONTHS, JANUARY 1 TO APRIL 1, 1888.[1]

SERVICE OF DR. W. E. BOARDMAN.

IT is my privilege to inaugurate the custom of rendering to this Society a quarterly summary of the service at the Hospital. From this and succeeding reports it is believed that some, possibly much, information of value may be derived. You are quite familiar with the class of patients which are received there, and the profession, generally, is now well informed as to the routine methods of treatment pursued, which have been so clearly described by my colleague, Dr. Richardson, in a paper recently read before this Society, which shows conclusively to our minds the value — indeed, the necessity—of aseptic and antiseptic precautions in midwifery, a conclusion which the experience herewith presented will serve to emphasize, comprising, as it does, the largest number of patients confined at the Hospital in any quarter-year, and including a large proportion of complicated and serious operative cases, all of which recovered promptly without alarming symptoms. Indeed, the only case of evident protracted septicæmia was that of Jessie M., whose labor was normal, and whose temperature did not begin to rise until the eighth day of convalescence, when it was determined that the disturbance was due to a malposition of the uterus, which occasioned an obstruction to the escape of the lochial discharge from the cervix.

I deem it proper to state that the very successful issue of all the cases was largely, if not chiefly, due to the intelligent, efficient, and unremitting care of the internes, Drs. Mead, Paul, and Yage.

Primiparæ, 77; multiparæ, 35; total, 112. Married, 58; single, 54; total, 112.

PREMATURE LABOR.

Primiparæ — 1 8 mo. 2 7 mo. 1 6 mo. 1 5 mo. 1 O.L.A. 1 O.D.P. 2 Footling. 1 Breech.

Multiparæ — 2 7 mo. 1 O.L.A. 1 unknown.

Abortions none.

Labors: natural, 94; laborious, 8; complex, 5.

Forceps were applied in seven cases: in four instances the high operation was done.

Version after manual dilatation of the os was done in two cases, and attempted in a third case where the os was fully dilated. Eclampsia occurred in one of these cases.

There was one case of complete placenta prævia.

Craniotomy was done upon the dead fœtus, once on the after-coming, and once on the presenting head.

Twins occurred only in one instance.

These cases are given somewhat in detail later on.

Average duration of labor: primiparæ, 24 h., 3 min. (first stage, 22 h., 45 min.; second stage, 1 h., 25 min.; third stage, 11 + m.); multiparæ, 28 h., 7 min. (first stage, 27 h., 27 min; second stage, 22½ m. third stage, 10½ m.) — one case, 147 h., 30 min., and another, 286 h., 45 min.

Urine (taken on entrance): albumen found in 29 cases, and casts in one (Case III), described later.

Maternal pulse: average after completion of second stage, 84⅜ (highest, 144, lowest 60); average after third stage, 86⅜ (highest 144, lowest 60). The highest rate was in Case V, with placenta prævia.

CHILDREN.

Whole number, 113.

Fœtal heart averaged 136 + (highest, a girl, 178; lowest, a boy, 110). Boys' average, 136 +; girls' average, 135 +.

Sex: 58 male (43 primiparæ, 15 multiparæ); 55 female (35 primiparæ, 20 multiparæ).

Length, average: male, 21.1 in.; female, 21.06 in. Longest (female), 24 in.; shortest (male and female) 17.5 in. each.

Weight, average: male, 7 2-16 lbs.; female, 7 1-16 lbs. Heaviest (male), 10 5-16 lbs.; lightest (male), 5 lbs. Average gain in weight, .31 oz.; greatest gain, 19 oz.; greatest loss, 21 oz.

Cord: average length, 24.3 in.; longest, 37 in.

Placenta: average weight, 21 oz.; heaviest, 36 oz.

Cord came off: average, 7 16-23 days; longest time, 14 + days; shortest, 4 days.

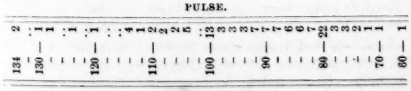
Ophthalmia occurred in two cases, and yielded readily to treatment with calomel dusted between the lids.

Puerperium: there was a mild cystitis in one case, relieved by catheterizing in a few days.

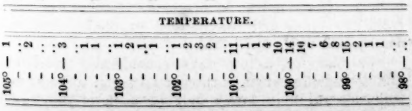
The catheter was required to relieve retention in 19 cases. The breasts were supported in 28 cases, and 7 cases had sore nipples. There occurred but one case of septic trouble which occasioned any anxiety, the one to which reference has already been made.

The following table gives a summary of the temperatures and pulse, and in connection therewith it should be stated that the number of high temperatures must not be considered as indicating an equal number of septic cases, for most of them were instances of a temporary rise from emotional or other neurotic disturbances — the passage of large fæcal masses and like trivial causes. The scope of this paper will not permit a more detailed analysis to substantiate this statement.

PULSE.



TEMPERATURE.



Uterus. Examination made before discharge from Hospital (not all examined). Position: left lateral version, 2; right lateral version, 1; anteflexion, 27; anteversion, 51; normal, 15. Cervix: right lateral laceration, 31; bilateral laceration, 30; stellate laceration, 3; normal, 34. Average depth of uterus, 3½ in.; greatest depth, 5 in.

CONDITION OF PERINEUM.

	Intact	Old tear

IV "	1	2
VI "	..	1
VIII "	..	2
IX "	..	2
Total	26	19

Nicked 31, united 17, not united 14.

Lacerated and stitched 31, united 18, partially united 10, not united 3.

Average stay in Hospital after confinement, 14 + days; longest, 53 days.

Mortality: maternal, 0; infantile, 1 (a premature seven-months' child, which was born asphyxiated, but was resuscitated and lived three hours).

Stillbirths, 9. Seven of them were premature; and one of these, and another at full term, died in the process of artificial delivery, and craniotomy was done later. The ninth case was the child of CASE VIII, referred to later.

The mothers were all discharged well except, of course, some of them were debilitated. The children were all discharged well.

The following cases are referred to as presenting points of interest:

CASE I. Elizabeth B., I para, single. Confined February 19th, O. D. P. First stage, 8 h., 50 min.; second stage, 1 h., 35 min. Head delayed at perineum, and Largenwitch forceps applied by Dr. Boardman. Child had cephalhæmatoma. Mother and child discharged, well, March 3d.

CASE II. Elizabeth G., I para, single. Confined February 19th, O. L. A. First stage, 32 h. Largenwitch forceps applied at brim. Mother and child discharged, well, March 3d.

CASE III. Sophia F., I para, single. Confined February 22d, O. L. A. First stage, 25 h., 45 min. (membranes artificially ruptured); second stage, 1 h., 15 m. Head delayed at perineum, and short forceps applied by Dr. Mead. Mother and child discharged, well, March 6th.

CASE IV. Marion M. K., married, thirty-one years old, I para. Confined January 30th, O. D. P. First stage, 49 h., 10 m.; second stage, 2 h., 6 m. Pelvis: external conjugate 7¼ in.; crests 9½ in.; anterior superior spines, 8 in.; diagonal conjugate, 3 in. Membranes ruptured before entrance. For seventy-two hours had good pains; os not dilating, cervix taken up. Then had convulsion. Urine smoky; albumen, ⅛ %. Two more convulsions, partially controlled by ether. Etherized seventy-eight and one-half hours after beginning of labor; os a pin-hole. Dilation begun by Dr. Boardman with sponge-forceps at 2.10 P. M., and carried on with bone-forceps. Then manual dilation was begun: the hand was pushed with much difficulty through pelvis. A rest of fifteen minutes became necessary to recover strength and control in the hand, which was introduced again and the right foot seized and brought to vulva at 3.20 P.M. Traction on child and pressure over uterus were employed. Hot cloths to child; the fœtal heart beating from 160

to 180. Child born to shoulders easily, but the head was arrested at the brim. Traction and forceps proved unavailing, and at 3.55 the skull was punctured with Smellie's scissors just behind right ear. The cranioclast could not be applied and the blunt hook was introduced, and by traction with this the head was born at 4.16 P. M. A hot vinegar douche was given to prevent hæmorrhage. Retention till February 3d, requiring catheterization. Discharged, well, February 20th.

CASE V. Nellie M. K., VIII para, thirty-four years old, married. Labor began February 14th, at 7 A. M., at her home, where she had, as stated, a very profuse hæmorrhage. Physicians were summoned, and the vagina was tamponned with a sponge and a colpeurynter. Entered the hospital at 6.40 P. M, when she was extremely weak and blanched, with a variable pulse from 120 to 140. Fœtal heart could not be heard. The tampons were removed without inducing hæmorrhage, and the os found dilated to size of seven-eighths-inch and dilatable. Complete placenta prævia was determined. Without delay I commenced manual dilatation of the os. As the vagina was very capacious and the os dilatable, no ether was administered, as I thought the patient's chances would be better without it. She did not utter a word; indeed, scarcely gave an expression of distress during the operation, which was readily done. The right foot was seized. A little delay was occasioned by the obstruction to the version by the hand and head. Child born in thirty-five minutes after commencing manual dilation, and found to be macerated, about eight months old. Placenta and membranes came away entire. Mother discharged, well, March 12th.

CASE VI. Elmira B., I para, twenty-five years old, married. Confined March 13th, O. D. P. First stage, 20 h., 50 min.; second stage, 5 h., 26 min. Head was delayed for three hours on perineum, when it was delivered, face to pubes, by Dr. Paul. Mother and child discharged, well, March 26th.

CASE VII. Lizzie B. (col.), I para, thirty-five years old, married. Had multiple fibroids. No history of menorrhagia prior to pregnancy. One tumor, with a pedicle, the size of an orange, could be felt in the epigastrium. Three smaller ones, without pedicles, projected from the left of the uterus. None could be felt per vaginam. Twins were diagnosticated by the sounds of the fœtal hearts. The first presented S. L. A. Little progress having been made for eleven hours, when the os was about two-thirds dilated and the membranes ruptured, while the patient was partially under the influence of ether, I brought down the right foot. The sacrum rotated posteriorly to left, and left foot was released. The body continued to rotate, and came out back to pubes. The child was soon born, partially asphyxiated, but was readily resuscitated. The uterus remained large, and the membranes of the second child were ruptured artificially, when it presented O. D. P. Labor continued to be slow, with inefficient pains. Ether was again administered, and the second child easily extracted with Largenwitch's forceps. A slight post-partum hæmorrhage ensued. The patient had an uninterrupted convalescence. The uterus remained large, measuring four and one-half inches in depth at the final examination, when the tumors could hardly be felt. Mother and children discharged, well, March 26th.

CASE VIII. Mary C. S., twenty-eight years old, I para. Entered, in labor, March 14th, when fœtal heart was heard beating normally. Patient did not have severe pain, and her general condition presented nothing unusual. Two hours, forty-five minutes, after entrance, upon auscultation, no fœtal heart could be heard. In the interest of the child, I immediately proceeded to manual dilatation of the os, which was then one and one-half inches wide, and ruptured the membranes, giving escape to liquor, mixed with meconium. Largenwitch's forceps were applied at the brim, and the child was extracted, still-born. There was some little delay in getting the head through the superior strait. Possibly, had I at hand an axis-traction appliance, the result might have been more favorable, though the mixture of meconium with the amniotic fluid would indicate otherwise. The placenta was normal in appearance. An autopsy upon the child showed no cause for its death, but the head was not opened.

CASE IX. Matild R., I para, married, thirty-two years old. Labor began March 15th. Membranes ruptured, 2 A.M., March 16th. Brought to Hospital from East Cambridge, 8.40 P.M., March 18th, when I found the os fully dilated, with the head presenting, O. D. P. Fœtal heart, 178; mother considerably exhausted; pulse 108; temperature, 100.2°. Inspection of abdomen showed a marked prominence above, on left side, and another below the umbilicus, on right side, suggesting twins; but only one fœtal heart could be heard, on right side, below the umbilicus. A deep sulcus could be plainly defined between the two masses. Per vaginam, the os was found to be quite fully dilated, the anterior lip elongated and œdamatous; head presenting, O. D. P., and just entering brim. At 9.15, under ether, version was attempted; but I was unable to get my fingers beyond the line of the sulcus mentioned, which was due to a constriction at about the junction of the middle and lower third of the fundus. It will be remembered the membranes had ruptured at 2 A.M., March 16th, two days and more before. After continuing for some time, without effect, my efforts to pass this constriction, I withdrew my hand, and applied the Vienna forceps; but these slipped. Then I endeavored to use Reynolds's axis-traction rods; but the fenestræ of the forceps were so high and jammed at the brim, that I could not introduce them. Largenwitch's and Pajot's forceps were then tried with the same results. Meanwhile the patient's pulse had risen steadily to 160. The fœtal heart could no longer be heard, and craniotomy was begun. Just as a perforation had been made, the patient ceased to breathe, her face and extremities became black, and the pulse ran up to 170. She was immediately placed with head down and limbs elevated to the perpendicular, and stimulants were given subcutaneously. Considerable liquid ran from the mouth, presumably, too, from the trachea, and respiration was resumed. She was then replaced upon her back, with the head dependent, and delivery was soon accomplished by the cranioclast. Pulse 120. Ergotine was administered subcutaneously, and hot vinegar was injected into uterus. The uterus contracted slowly. There was but slight hæmorrhage after removal of placenta. She rallied well from the ether and convalesced gradually, and was discharged, well, April 7th.

She had for a few days considerable persistent and distressing cough, with coarse, moist, sibilant, and sonorous râles in lower half of back of lungs and

lower half of left front, with muco-purulent expectoration. An abscess formed in right forearm at the seat of the subcutaneous injection of ergotine. At the time of her discharge the uterus was still large, with a depth of five inches and a right lateral laceration of the cervix. Measurement of the pelvis gave between anterior superior spines, 8¾ in.; between crests, 9¾ in.; external conjugate, 6¾ in.; diagonal, 4 in.

THERAPEUTIC NIHILISM.[1]

BY MAURICE D. CLARKE, M.D., OF HAVERHILL.

It has been said, and perhaps not altogether without reason, that what Matthew Arnold would call the stream of tendency of modern medical thought was toward a therapeutic nihilism, — at least in Boston. Now, if by nihilism in therapeutics were meant anything like the chaos the word implies, the charge would carry with it its own refutal. But, if the men that are fond of the phrase therapeutic nihilism, mean by it that our creed is that of *laissez faire*, that our attitude by the bedside is one of folded hands, that, in short, we are willing waiters and not workers, we may well plead to the indictment.

Doubtless there is something captivating in the phrase itself, since it stands out in evident contrast to the general instinct of humanity, testified to no less by the domestic thoroughwort and saffron than by the munificent hospitals and dispensaries of a larger charity, to do something for the sick. Whether to do something is necessary or not, whether it is wise or not, whether it may not be even harmful, we all understand that it is expected of the physician, by common consent, to do something. How often, too, after having inquired as to the patient's bodily functions, regulated the diet, made suggestions as to bed and bedding, urged the importance of fresh air, and carefully attended to all the minute details for the patient's comfort, how often has it fallen to the lot of all of us to be confronted by the anxious friends with the inquiry, "But aren't you going to do something for him, doctor?" It is equally a matter of common knowledge that this widespread sentiment of the laity finds its echo among physicians, and that a large majority of them share the opinion that he fails of his duty and his privilege who neglects to do something. The alleged nihilist in therapeutics antagonizes, therefore, a rooted prejudice, not alone in the world at large, of whom nothing else need be expected, but among his own class, who might be presumed to exercise an intelligent judgment.

I remember very well that the somewhat jejune proceedings of the Section of General Medicine of the International Congress at Washington last fall were refreshed one afternoon by a discussion on therapeutics, in which varying views were presented with an approach to animation. No speaker, however, met with a heartier reception or provoked louder applause than a gentleman from Ohio, who announced himself as an enthusiastic believer in active medication and in the new drugs, and who pointed his remarks by the terse statement that, whereas rheumatic fever used to mean Dover's powder and six weeks, it now meant salicylic acid and six days. The man and the approval are typical. There can be no doubt that the popular current sets this way. It is the positive dogmatist that catches the public ear, and negations fail of attractiveness as they are difficult of proof.

I suppose there are few pursuits whose study and practice are characterized by so much zeal as that of the physician. The zealous medical student has become a proverb. And it is excess of zeal that has obscured and continues to obscure the exercise of a reasonable therapeutics. Each new drug that the botanist finds in the fields, the chemist in the retort, becomes to the ardent experimentalist an immediate specific for not one disease but many. It was so in the days of our fathers, it is so now, it is very likely to be so for some time to come. There is just dying from our midst the last of a generation that revered the lancet, and many of whom used to find their own materia medica in their neighboring woods and fields. The place their valued remedies held was usurped yesterday by antipyrin, the day before by cocaine, and will be to morrow by I know not what. It is stated in the current medical literature, with every appearance of truth, that cocaine, for example, is "good in," to use the every-day phrase, gastralgia, childbirth, seasickness, nasal hæmorrhage, hay fever, rhinitis, hæmoptysis, etc.; while antipyrin is very fortunately useful in spermotorrhœa, pertussis, enuresis, locomotor ataxia, rheumatism, migraine, neuralgia, seasickness, epilepsy, phthisis, hay fever, hysteria, lumbago, sciatica, diabetes, chorea and herpes zoster. But, alas, last week or last year the virtues of other drugs were lauded with equal assurance of their power. It is gravely stated in a dispensatory of the last century that "examples are related of very dangerous phthisis cured by the continued use" of a conserve of red roses; and the tincture of amber is extolled as "having incredible efficacy in all those distempers which proceed from weakness and relaxation, and in hypochondriacal, hysterical, and cold languid cases."

But there are other causes operative to favor indiscriminate therapeutics besides the popular clamor for dosage and the professional tendency to energetic medication. Not the least of these is the vast number of physicians annually sent out by the schools, which, in the nature of things, must include many excellent blacksmiths and tradesmen. "In this country," says the president of the American Medical Association in a recent address, "the multitude of medical schools, offering to the educated and uneducated, by low fees and short terms of study, inducements to become doctors, together with the almost universal desire among laborers to become doctors, has worked incalculable mischief. We have waited almost half a century for the desired reform to be effected, but our expectations have not been realized. Many excuses have been brought forward, but there is no excuse which will free the medical schools of this country from the responsibility of the odious defects of our system of medical education. The ratio of professional men in the United States to the population exceeds that of any other country in the civilized world. The ratio of practitioners of medicine to the population of the United States at present is about one to every five hundred and eighty, and there is very little danger that this ratio will be lessened. The supply will always equal the demand in spite of all difficulties." It is inevitable that the greater the rush to enter the profession the greater must be the proportion of those who, having but a smattering of general knowledge before matriculation and looking after graduation upon the practice of

[1] Read before the Massachusetts Medical Society, June 12, 1888, and recommended for publication by the Society.

medicine as a mere trade or means of livelihood, apply to it the same instincts and rules that govern the grocer's clerk and the carpenter's apprentice. It is inevitable that quinine and calomel should represent to them to-day the saw and scales they dropped yesterday, and that they should bring to the treatment of that complex variation from the normal we call disease the same confident energy they once employed in the building of fences and the weighing of sugar.

So far, indeed, as the representative school of New England, in which some of us have a personal interest and pride, is concerned, it is well understood that it is not open to criticism of this sort. I am not disposed to affirm, nor would it affirm, that its curriculum is complete or its methods incapable of improvement. I have heard the complaint in years past that its graduates had learned much about medicine, but had failed to learn how to practise it; that they had been taught the science and not the art of therapeutics; and that, when they were brought face to face with the every-day exigencies of private practice they found themselves at a loss. Now it may easily be that the student of the earlier days, riding his rounds with the country doctor, found something in the personal acquaintance with his instructor and his instructor's methods, in the daily elbow-touch with his parishioners, in the actual sharing of the interchanging hardships and rewards of a physician's life, — found something that the modern medical school, even with the aid of hospital and dispensary, fails in the nature of things to furnish him. And it may well be that the modern medical school would do wisely in adding to its scheme a few lectures upon the practical side of medicine before turning its graduates loose upon the community. But this is not saying that the modern medical school holds a wrong attitude toward therapeutics, if, inclining neither to the rhapsodies and vagaries of the enthusiast on the one hand nor to the idle fatalisms of the sceptic on the other, it aims to teach only such things as are believed to be truths in medicine, and leaves its students to deduce from them right conclusions.

The fact is that the treatment of the sick is very largely a matter of temperament. Some men are naturally disposed to look at disease from the standpoint of preventive medicine, some from that of hygiene, some with a reverence for the *vis medicatrix naturæ*, some with a belief in active medication. And the latter position is certainly the most attractive to the average medical man, and, in the presence of any serious illness, it is the most acceptable to the laity, in spite of the popularity of that therapeutic opera bouffe, homœopathy. Again, some men incline to run after new fashions, treating all diseases impartially and indefatigably with the newest discoverable drugs, and endeavoring to keep up with the "samples" of the manufacturing chemists; this is experimental therapeutics. Others, tor inert, perhaps, to shift for themselves, leave to these the practice of experiment, but borrow from them the suggestions their results afford; this may be called vicarious therapeutics. Others, again, settle back into the comfortable habit of always giving the same thing for the same disease, and thus, having once been in travail and delivered of a diagnosis, have nothing left to do but consult their books or their memories for the indicated remedy; this method of practice, I suppose by far the most common and certainly the most degrading of all, is routine therapeutics. There are a few physicians, however, who look upon each case as to a certain extent *sui generis*, and who bring to its relief not only the results of the experience of the past and the experiments of the present, but also a personal opinion of the needs of the particular case, and who, so far as they are let, endeavor to do what a sound training, an impartial judgment, and an active conscience command; and this seems to me rational therapeutics.

I am aware that what I have said has been said before, and much better than I can say it. In fact, something like it was said fifty years ago before this Society by Dr. Jacob Bigelow, whose later writings repeat and emphasize the same idea. "It is the part of rational medicine," said he, "to require evidence for what it admits and believes. The cumbrous fabric now called therapeutic science is, in a great measure, built up on the imperfect testimony of credulous, hasty, prejudiced, or incompetent witnesses. . . . The enormous polypharmacy of modern times is an excrescence on science, unsupported by any evidence of necessity or fitness; and of which the more complicated formulas are so arbitrary and useless, that if by any chance they should be forgotten, not one in a hundred of them would ever be re-invented. And as to the chronicles of cure of diseases that are not yet known to be curable, they are written, not in the pages of philosophical observers, but in the tomes of compilers, the crudities of journalists, and the columns of advertisers. . . . The exaggerated impressions now prevalent in the world, in regard to the powers of medicine, serve only to keep the profession and the public in a false position, to encourage imposture, to augment the number of candidates struggling for employment, to burden and disappoint the community already overtaxed, to lower the standard of professional character, and raise empirics to the level of honest and enlightened physicians."

There existed, indeed, in that day something that has fallen into disrepute in ours, and that is a belief in "heroic" medication. Active drugging does, to be sure, exist in plenty, but "heroism," in the sense of the exhibition of large quantities of nauseous medicine, no longer fetters the profession or frets the patient. Neither form of error, however, was spared by Dr. Bigelow's incisive pen. But this paper will not have altogether failed to be of service if it does no more than call attention, in these days of polypharmacy and superpharmacy, to truths which may have gained theoretical acceptance but failed of practical realization. The lesson cannot be said too often. No less an enthusiastic therapeutist than Roberts Bartholow has stated within three months, that "the science of therapeutics should be made more certain. This is a branch of medical study which is not cultivated as it should be, and a true knowledge of drug action is not widely enough diffused. The acquisition of this knowledge is greatly hindered by the mass of old prejudices which still cling to this science and impede its progress, like the barnacles on the hull of a ship. All this complexity and superfluity of olden times must be wiped away; at least two-thirds of the pharmacopœial preparations could be dispensed with, and scientific therapeutics would thereby be the gainer."

There appeared last fall a series of delightful reminiscences, personal and professional, from the pen of an honored member of this Society, whose ripe years

included a half-century of practice, from Laennec and Louis to Koch and Pasteur, who had seen the swift-handed surgery he was taught revolutionized by the discovery of ether, and who might have heard the then novel doctrine of the self-limitation of disease from the lips of its learned propounder. In his earlier days, to use his own words, "a doctor's call meant something. An emeto-cathartic inevitably followed the first visit, no matter what the disease might be." The doctor "was called to do something at once, and he generally did it." His "course was simple and easy. He had to be 'heroic' only with the lancet and heavy doses, and his responsibility was cancelled. If successful he had been lucky in hitting upon the right medicine; if unsuccessful, it was the patient's misfortune. . . . But, alas for the cautious or unheroic practitioner. His failures were accounted no better than homicides, if not indictable." When a man of this training and experience, at the close of fifty years of practice, publicly suggests as a fitting and self-desired inscription for his tombstone, "He cured the sick without drugs," it has occurred to me that we might be justified in occasionally neglecting to do something.

Yes, I repeat, if by therapeutic nihilism is meant that we are mere lookers-on in Vienna, none of us will admit that such is an attitude we keep or desire. But if it is charged, that in the presence of disease we maintain at once a reasonable faith and an honest scepticism; that we decline to fire at random and with all sorts of shot, in the childlike hope that Providence will kindly let us hit something; that, in short, we intend, as St. Paul advised the Thessalonians, to prove all things and hold fast that which is good,— then there are those among us, let us trust, who stand just there, unmoved by the ebb and flow of the tides of ignorance and prejudice. And why not? For, as Van Swieten said, a century and a half ago, in his Commentaries on the Aphorisms of Boërhaave, the learned professor of Leyden: "What will be the idea of the best Physician in future times we know not; but he is to be reckoned a good Physician now, who makes use of all the assistances by which, through the happiness of the present age, the art of Physick has been improved."

Clinical Memorandum.

UNUSUAL SUSCEPTIBILITY TO SEDATIVE REMEDIES.

BY ALBERT N. BLODGETT, M.D.

The following case, which recently came under my observation, presented some features of peculiar interest, and I venture to record it:

The patient, a lady of twenty-four, in good health and free from any unusual tendencies, consulted me in relation to an acute neuralgia affecting the distribution of the facial nerve on the left side. Quinine in considerable doses, averaging ten grains a day for a few days, was sufficient to entirely relieve the distress, and the patient was for a time free from all disturbance.

The lady was in the fifth month of pregnancy, and again consulted me on account of a burning and smarting sensation following urination, which was very frequent, and occasioned much suffering from a constant pain in the back, hips, and at the orifice of the urethra. The patient stated that she had been for a time a guest at a well-known watering-place, and that many of the ladies there were affected in a similar manner, and that the general opinion had been formed that this was in some way due to the waters, although many of the guests had been formerly at the same place, and had never had occasion to complain of the action of the waters. The pain and distress were so severe that my patient left the place, and after some delay, in the hope that the trouble would spontaneously subside, consulted me, as above stated.

I made no local examination, but prescribed a solution of bicarbonate of soda, containing to each teaspoonful two grains of potass. brom. sodii. brom. and chloral hydrate, with the addition of one-twentieth-gram of morphia. This solution was prepared at six o'clock in the evening, and the patient took one teaspoonful at half-past six, one at half-past eight, one at 2 A. M., and one at 8 A. M. She slept in the intervals, but awoke at the times stated, and, as she was alone, there is no other probable way in which the medicine could have been administered, except by her own hand. At eleven of the day, she rose and dressed and walked about her apartment, but feeling very drowsy and becoming rather frightened, she telegraphed for her husband, who came to her at four o'clock. She was at that time sleeping soundly, could with difficulty be wakened, and had no idea of the time, of her surroundings, or of the circumstances attending her condition. I was quickly summoned, and on reaching the patient found her dressed, seated in an arm-chair, and sleeping, with her head resting upon the back of a chair. Her color was good, there was no lividity of the skin, the breathing was easy, free, and natural, the pulse 72 and free, the skin a little cool, pupils dilated and sensitive, and the patient's condition was in no way otherwise changed from the appearances of ordinary healthy sleep. On trying to arouse her, there was no response to gentle measures, but by more vigorous methods she was sufficiently roused to open her eyes, to answer questions, and to give an account of her experiences. Two drops of the ordinary tincture of nux vomica were prepared in a little water, and the patient made to swallow it. She was then forced to walk, and after a little time could stand, and was able to move by herself. On being left alone, she at once sank down without regard to her situation, and was immediately asleep, and had to be violently roused. About five minutes after taking the nux vomica there was a distinct tetanic convulsion of a moderate degree of intensity, which was not, however, repeated. She now began to show increased animation, and was soon able to go about unassisted, and at my advice was taken to walk in the open air. She had eaten nothing during the entire day, and after a half-hour was able to take a good dinner, and from this time was entirely free from any soporific influence.

The patient said afterward that she had once before been similarly affected by a small amount of medicine given by a physician which contained bromides. She did not know the composition of the present medicine, and had no idea that it contained these articles. There was no appearance of hysteria, and the case seems to be one of unusual susceptibility to the action of a class of drugs which are usually supposed to be comparatively mild in character, and to be safe in large doses.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M. D., SECRETARY.

MAY 12, 1888, the President, DR. WILLIAM L. RICHARDSON, in the chair.

DR. W. E. BOARDMAN read

A REPORT OF THE CASES DELIVERED AT THE BOSTON LYING-IN HOSPITAL DURING THE THREE MONTHS JANUARY 1ST TO APRIL 1ST, 1888.[1]

DR. LYMAN remarked that a large proportion of the cases had albuminuria, and asked if any of these cases presented serious symptoms. The reader replied that there were no symptoms in any case except one: that patient had eclampsia.

THE PRESIDENT said that fourteen years ago, when he supposed that albuminuria meant approaching eclampsia, he had made a series of observations bearing on this subject. The urine of every patient was drawn by catheter before labor, when time permitted, and examined: in the first thousand cases albumen was found in forty-three per cent.; but in the vast majority of this proportion nothing else was found, and the albumen disappeared soon after labor.

DR. EDWARD REYNOLDS said: I have been especially interested by two points in Dr. Boardman's report. He finds, if I understood him correctly, that in seventy-seven primiparæ the average duration of the second stage of labor was only one and one-quarter hours. This is somewhat shorter than is usually reported, and is the more remarkable from the fact that in a hospital where the house physicians do not apply forceps unless in the presence of the visiting physician, the length of the second stage is always prolonged in operative cases by the time consumed in sending for him. Should further statistics support this average, it would lend additional emphasis to the opinion held, I think, by most of us, that a three-hour second stage is long enough for any woman, and that if at the end of two hours the head is within the pelvis, and is not advancing, it is better to apply forceps at once in advance of the coming exhaustion, rather than to delay until mother and child are in a precarious condition; and I think it is evident that in so doing we are following rather than supplanting nature, for if the powers of mother and child have been arranged for resisting the strain of the normal second stage of from one to two hours, it is plain that any considerable further delay must imply a drain upon that surplus strength, the expenditure of which results always in exhaustion.

I wish further to suggest a remedy for the difficulty which Dr. Boardman found in adjusting my axis-traction rods to the forceps in one case. As a rule nothing is easier than this attachment, but in a few of those cases in which the head is free above the brim of a transversely contracted pelvis I have found the fenestræ so high and the blades so closely approximated to the pelvic wall that there was not sufficient space for the passage of the rods; but, if in such a case the forceps be unlocked, the fenestræ are found to be then within reach, and the attachment of the rods again becomes a perfectly easy matter. I have now used the rods in five such cases, and have seen them used in equally difficult cases by two other physicians, neither of whom had ever applied them before, and in no case was there any real difficulty in attaching them. I cannot help thinking that by this expedient they can be applied in any case which is at all suitable for forceps.

DR. J. P. REYNOLDS reported some cases of interest.

DR. SINCLAIR thought the reader should be thanked for his teachings of early delivery in placenta prævia and eclampsia.

DR. FIFIELD, present by invitation, asked whether any members had had experience with veratrum viride in eclampsia. Jewett, of Brooklyn, had lately recommended the drug, and had found that subcutaneous injections of 15, 25, or 30 minims had a wonderful effect in quieting the convulsions. Some years ago Dr. James Sullivan, of San Francisco, recommended veratum viride combined with grain one-quarter of morphia: Dr. Fifield himself had never known the drug to be used here.

DR. MINOT asked if venesection had disappeared from among our various methods of treating eclampsia: he had had occasion to bleed on several occasions, and thought bleeding a valuable expedient in some cases. Certainly a large amount of urea might be removed by the bleeding; and if the blood is filled with poison, the removal of much of it must be a desirable thing.

DR. J. P. REYNOLDS queried whether a single bleeding might not be advisable when in primiparæ there are difficulties of dilatation: would not dilatation be facilitated thereby?

DR. C. E. STEDMAN had, in early years, practised venesection with success, even in one desperate case in which the patient was already anæmic, and who, he believed, was saved by free bleeding. The indications he had followed were headache and a full bounding pulse: he bled to twelve or sixteen ounces. Venesection was now largely superseded by anæsthetics.

DR. FIFIELD remarked that if done at all bleeding should be done freely. The rapidity of the pulse before a convulsion had probably led to venesection, and then to opium; but veratrum viride will also slow the pulse, and ought to give good results.

DR. BLAKE suggested that in successful results attributed to bleeding or veratrum viride the happy issue was in great measure due to the termination of the labor.

THE PRESIDENT said that those who bleed in eclampsia use other treatment at the same time, and he believed the success was due to the other treatment: the same was true of veratrum viride. He had seen many cases of eclampsia in consultation practice; but only one had proved fatal, and that one was bled.

DR. LYMAN said that before ether was known opium was looked upon as a bad thing in eclampsia, and the convulsions were treated by bleeding: then came ether. Then the profession, in New York especially, gave morphia: now come morphia and veratrum viride in combination. All these remedies are probably good, singly or in combination according to the case: there is no one remedy for all forms and conditions of eclampsia.

[1] See page 196 of the Journal.

BRITISH MEDICAL ASSOCIATION.

GLASGOW MEETING, AUGUST 7-10, 1888.

DR. J. T. BANKS, of Dublin, the retiring president, occupied the Chair, and opened the 56th annual meeting with a few remarks. He congratulated the association on their meeting in Glasgow, now become the second city of the empire, and assured them a hospitable reception in the ancient University. The past year had been one of prosperity in the association. One year ago when he became president the membership was 11,000; now it is 12,000. He congratulated the association heartily on the selection of Prof. W. T. Gairdner, of Glasgow, as president for the present year, and introduced that gentleman to the association.

PROFESSOR GAIRDNER, on taking the Chair, said that he would not boast on putting on the armor; it was not the time. It was the occasion, however, for Professor Banks to boast, for his work had been accomplished. Professor Gairdner said that though it was too early to boast, it was not too soon to be thankful for the honor conferred on him by the association in electing him to the Chair.

Council reported new branches, as follows: Perthshire, Nova Scotia, and Cape Town, South Africa. Two others in Tasmania and Malta are about to be formed. The number of members on the register last year was 11,107. During the year 359 resigned, 132 died, 1649 new members were elected. Present number, 12,265. Income £28,680; expenditure £26,060 17*s* 9*d*. Surplus £1,619 2*s* 7*d*.

Inebriates Legislative Committee made a lengthy and encouraging report, which was adopted. They had changed the name of the act from Habitual Drunkards' Act to Inebriates' Act. Many declined to be called habitual drunkards, yet acknowledging themselves inebriates, and many were not habitual in their dissipation, but periodic. The legislation is now permanent in place of the temporary act for ten years which has just expired. In Great Britain, as well as in the United States and in the colonies the move towards this object has been originated among medical men.

Services were held in the old cathedral, which was crowded to its utmost with doctors, who sang the One Hundredth Psalm with a will. The sermon, by Principal Caird, was a counterblast to modern materialism. He dwelt at some length on the arguments to be deduced from death and the loss of reason, and concluded by two objections absolutely fatal to the materialistic theory of the relation of matter to life. First, the theory was in irreconcilable opposition to the very law of the conservation of the energy on which it professed to rest. Further, the fundamental objection to all material theories was that they begged the question at issue.

A resolution, stating it to be the opinion of the association that Irish and Scotch diplomas should possess the same privileges as diplomas from other divisions of the United Kingdom, which was brought up at the Dublin meeting one year ago, passed unanimously.

PROF. W. T. GAIRDNER, of Glasgow, then delivered

THE PRESIDENT'S ADDRESS.

He took for his subject "The Physician as Naturalist." In no other language he said, besides our own has the title physician or physicist survived and threatened to engulf the term medicine, the art of healing. The physician is regarded as a student of nature. It is hard to find where this idea first took shape.

For a series of interminable ages, from the time, perhaps, of Hippocrates downwards to what we call the Dark or Middle Ages, the tradition has continually existed that the healer or physician of the highest class ought to be in every sense of the word a student of nature, a naturalist, or perhaps a man of science, and that he is trustworthy as a healer or physician chiefly in proportion to the confidence reposed in him as a naturalist, that is a humble, reverential and exact follower or student of nature. That magnificent opening of "Novum Organum" describes man as the minister and interpreter of nature. He must be, according to Hippocrates, the servant of nature. Hippocrates was the first to observe nature and her works. This term, servant of nature, according to Galen, will only apply to the true healer, and not to the mere druggist, who might be called the enemy and adversary of nature and the sick.

The physician of the middle ages, so far as we can judge of him from literature, while retaining the name, was in a very small degree, if at all, cultivated according to the type. In fact, anything like original research was dangerous on his part, and liable to be punished by imprisonment, perhaps the faggot. I apprehend that the physician of the middle of the seventeenth century in France unless caricatured out of all recognition by Molière, must have been altogether the most stupid, pompous and brainless formalist that ever in any age practiced the art under a learned title. Even down to the last century men of the type of Minacre and Cairns in the Royal College of Physicians in London, greatly predominated over the men of Science as exemplified by William Harvey. The physician *naturæ studiosus* was in danger of being wiped out, but the revival came, and in the Scottish universities chemistry as a science, and perhaps botany have never lost a distinctive place in the medical curriculum from that day to this. I wish I could say the same of physics proper, natural philosophy as we call it, which has been, comparatively speaking, left out in the cold. During the one hundred years past Scottish universities have been, with more or less success, laboring, on the whole, to build up again the great and noble idea of the physician as naturæ studiosus, a nature seeker, *natur forscher*. It has been claimed that the spirit of modern science is ungenial and hard, even pitiless, and therefore not at all fitted for the ministrations of humanity, that it tends to make the suffering man a mere case, a thing to be observed and noted rather than a man of like passions with ourselves, and therefore to be treated with consideration and sympathy. There may be just a grain of truth in this, yet all the evils inflicted on suffering humanity by the physician as scientist have been but a drop in the bucket as compared with those which have sprung from the too lavish adoption of traditions in which there never was any trace of the scientific spirit at all.

When we consider that the most of the great advances of the present day, stethoscope, microscope, laryngoscope, ophthalmoscope, sphygmograph and electricity involve applications of pure physics, which

are neither very remote from practice or yet very easily mastered by the beginner, and that in the case of electricity and other physical reagents, even heat and cold, we are every day extending the domain of these sciences in therapeutics, and still more, perhaps, in preventive medicine and sanitary science, their claim for an extended recognition in teaching seems to be enormously enhanced. I am persuaded that the physical laboratory will become an absolutely essential preliminary step in the education of the physician of of the future, and that those who have not undergone this training will be hopelessly distanced in the race.

He lamented the unprepared state in which most boys and young men leave school as regards the most elementary truths of physical science and the observation of nature. Twelve or fifteen hours per week are devoted to classics, and two or three hours are considered sufficient for science in most schools. This renders more than ordinary care necessary to insure at the very beginning of the medical education the preparation in physics which will shortly become all and in all to the true physician.

No child is too young to take in the a, b, c of science, the manner how and the reason why, as Kingsley puts it. Children should not be taken from the age of six from learning of nature and have their noses poked into books and papers for ten long years, till their eyes become myopic and their brains suffer a corresponding deformity.

Religio medici was next considered. *Ubi tres medici, duo athei*, is a proverb, the source of which it is impossible to trace, but which is evidently the growth of the mediæval period. This proverb is a calumny and a reproach. Yet to be accused of atheism in the Middle Ages might be the reverse of a real reproach to any man or set of men; to be tabooed for atheism has often been a compliment of the highest order.

The physician of the future, he believed, would be much more, instead of less, inclined to make his study of the Bible than hitherto. He will study it in the spirit of modern scientific freedom and historical research, and thus only, it seemed to the speaker, that the reconciliation of science and religion can ever be brought about.

PROGRESS OF SURGERY DURING THE LAST HALF CENTURY.

SIR GEORGE H. B. MACLEOD, of Glasgow, Scotland, took for his text in his address on Surgery the advances made during the reign of Queen Victoria. It was with pardonable pride that they spoke of medical science in this northern land and with no department of the one great and indivisible art have the names of Scotchmen been more honorably associated than with that which he represented. He cited the names of Lowe, Cullen, Black, Hope, Gregory, Graham, Granville, Pattison, Ure, Hooker. Balfour, Lister. The immortal Hunters were educated here. While in England 1 in 5,000 attend the Universities, in Scotland 1 in 500 avail themselves of this privilege. Of the 1,639 medical students registered last year in Great Britain, 666 belonged to the Scottish schools. After briefly sketching the works of the great masters in anatomy previous to 1847, Sir George took up the subject of "Anæsthetics and Antiseptics," which he considered to be the most distinguishing features of the period under review. They are both "epoch-making" discoveries. Each has done almost as much for surgery as the discovery of hemostatics, and when combined, may, I think, be said to excel even steam and electricity in their gracious benefits to mankind. Velpeau said in 1839, "All research for any agent to destroy pain in operations is a mere chimera and unworthy of further consideration." This was seventeen years before the great discovery. Suddenly, however, the riddle was solved, and by one who remembering the experiments of Humphrey Davy with nitrous oxide and sulphuric ether, dimly perceived the use they might be put to in surgery. Many of us can still recall the enthusiasm which that discovery evoked and the unbounded anticipations which it suggested. Chloroform was soon brought into use by Sir James Simpson. The relative merits of these and of other anæsthetics have not yet been determined. He himself, after fairly trying most of the agents in use, employs chloroform. He gives it in all cases and has never had an accident but once, when giving it to an epileptic he took a fit and died. It is unrivaled for speed and ease in giving. That it needs no apparatus but a towel is a great argument in its favor. He never measures the quantity used but exhibits it freely and takes the color of the lips and the respiration as his chief guides. Making the patient count at the beginning of the administration is a most valuable aid; and Nelaton's inversion of the body with artificial respiration is the surest mode of resuscitation in danger from failure of the heart. Anæsthesia has changed the whole aspect of surgery. "The lion heart" is now no more necessary for a surgeon. It was in this school that antiseptic surgery was first practically applied, so he may be pardoned if he speaks warmly and enthusiastically of that invaluable discovery. The fundamental principles on which it rests remain unassailable, and it has lead to practical results, not alone in its immediate effects, but in the discussions and and studies which it has produced, which have in an extraordinary degree, widened the domain of our art, diminished the sufferings, and saved innumerable human beings.

The study of micro-organisms which a quarter of a century ago were mere microscopic curiosities, has become a great and enthralling pursuit and has opened up a field of practical application, not in medicine and surgery alone, but hygiene and public health, though the present tendency is perhaps to exaggerate the influence of microbes. What was lately but a dream is capable of realization in the near future; namely, that every zymotic disease and all those which owe their origin to putrefaction and fermentation will finally be stamped out.

Aseptic surgery in its practical application has amazingly augmented the value of the surgeon's services. Pure drainage and entire rest, both physical and physiological, demand the attention of the surgeon. Of the many germicides he prefers the bichloride. Dry and elastic dressings have been most valuable improvements.

Hospital organization, owing to the misfortunes of the Crimean War and the cholera epidemic of 1852, have received more attention during the past twenty-five years than during the previous seventy-five years. That intra-mural hospitals are on their trial cannot be doubted. The smaller establishments in the rural districts meet the modern ideas more nearly than the

huge piles without space or pure air, which we find in the cities. Much good has been done during late years by the use of the ambulance wagon, after the American method, for the care of the sick and the instruction of the many in the care of the wounded.

To further abridge his address would be but to mention a long list of improvements.

An address before the general sessions which attracted unusual attention was that on

BRAIN SURGERY,

by William MacEwen, M.D., of Glasgow.

He said lesions of the head had at all times held a prominent place in the annals of surgery. The operations of primitive surgery were simple and chiefly directed to the superficial parts, the skull and its membranes. The brain inspired fear, as it was intimately associated with the seat of life, gave lodgement in its recesses to the soul and was surrounded with all the mysticism which speculative philosophy inculcated. From the day of Pott to our own, there seemed to be a growing conviction not only of the impotence but the positive harmfulness of active interference, so that the trephine was regarded as an almost obsolete instrument. Such was the state of surgery till 1870. It was necessary first to adopt means whereby immunity from the inflammation which so constantly attended brain lesions could be secured, and secondly, to endeavor to gain a better physiological knowledge hoping that light might be shed upon the localization of cerebral lesions.

The extended physiological knowledge obtained by the untiring efforts of such workers as Hughlings Jackson, Fritsch, Hitzig, and Ferrier, enabled cerebral lesions to be more accurately localized, while experience showed that by preserving aseptic the parts operated on, surgical interference could be robbed of its chief danger.

Here the history of a case was given in which the symptoms of focal cerebral disease led to diagnosis of lesion in Broca's lobe. This, unfortunately, had a fatal termination owing to the refusal of the parents to permit the operation, which was demonstrated after death, would have saved the life of the patient.

Dr. MacEwen then gave details of other cases, passing from the consideration of the Initial History of Cerebral Surgery to the Consideration of a Few Points regarding the Present Aspect of Cerebral Surgery.

His answer to the question whether the localizing motor phenomena are reliable guides to the diagnosis of cerebral lesions situated in the motor cortex, is unhesitatingly affirmative. Each case, however, must be studied upon its own merits. The various points of reliance should be tested wherever possible, by instruments of precision. When injury has been inflicted on the surface of the cerebrum, followed by plastic effusion and cicatricial formation, the superficial substance is apt to become soldered to the membranes, which in turn may become soldered to the skull, or if they should be detached the brain may become directly adherent to the bone by means of cicatricial adhesion. Thus the surface of the brain becomes anchored to its rigid walls. The gray matter of the cortex immediately surrounding the cicatrix is apt to become unstable, and traumatic epilepsy has thus resulted. If the cortical irritation be continued, encephalitis is sometimes produced and operation has occasionally hastened the fatal issue, encephalitis rapidly becoming general.

In the majority of instances the surgeon makes no effort to fill the gap caused by osseous defects in the cranial wall. Since 1873, he has carefully preserved the portions removed from the skull, rendered them aseptic, divided into minute fragments, and re implanted. These have grown wherever there has been immunity from suppuration. A most interesting case operated on four years ago was shown at the demonstration in the Royal Infirmary. Nearly one-half the left anterior portion of the skull was broken into fragments, which were mixed with brain-substance, shreds of membrane, hair, *débris* of lime and blood. The pieces of bone were all made aseptic, replaced, and, with the exception of two fragments, grew and now form a firm, osseous wall.

Briefly alluding to another portion of the nervous system, he said that certain sensory and motor phenomena due to lesions within the spinal canal are amenable to operations which are attended by a measure of success, which offers a prospect of relief to a class of sufferers hitherto regarded as hopeless. The spinal membranes and cord itself can be exposed, and neoplasms and encroachments upon the lumen of the canal may be removed therefrom without unduly hazarding life. In 1883, he first successfully operated thus for the relief of paraplegia due to angular curvature of the spine.

In conclusion, the distinguished speaker called attention to the fact that the same phenomena by which we are now able to recognize and locate cerebral lesions were exhibited by patients who came under the eye of our surgical predecessors, who were so hampered by the inculcated physiological dogma of the time that the facts were reflected from their brain as objects from a mirror, and their true significance never dawned upon them. There are all around us phenomena, each with its hidden truth obtrusively impressing our senses, and how do we fail to read their riddle?

A number of the patients operated upon by Dr. MacEwen were in attendance for examination by any of the members. All, both juveniles and adults, were in good health, the latter all able to be at work.

Dr. James C. Howden, of the Sunnyside Asylum, Montrose, the President of the Section of Psychology, in his address, touched on the lesson derived from the few cases of insanity in which surgical interference has resulted in recovery, and proceeded to discuss the medical and mental treatment of insanity. Insanity was a group of diseases of the most varied kind. Experimental teaching had done much good in showing the mischief of indiscriminate drugging, but it was apt to breed a fatalistic turn of mind. The importance of treating bodily diseases was duly recognized, and the individualization of patients and special medical treatment insisted upon. The training of attendants and nurses was now being carefully attended to. The moral treatment, though somewhat unfortunate in its sound, being somewhat Pharasaical, and implying the possibility of other means being immoral, was of much benefit, and there were few cases in which it could not, some time or other, be made use of. He preferred to call it mental treatment, as it was the effect of mental influence. It seeks to remove the patient as early as possible from the mental environments which produce or aggravate the disease. It seeks to distract the mind from

morbid feelings and thoughts, and seeks to occupy it with healthy employment and recreation. The prevention of insanity in its relation to civilization was discussed. The survival of the fittest would tend to eliminate insanity, and the highest civilization was the state which encouraged insanity by protecting the weak, and, at the same time, causing overpressure and injury to the brain. If the gospel of health could reach a civilized people, it would have a powerful influence in the prevention of insanity. He would look forward to the time when the brain would be so highly organized that false judgment and sophistical reasoning would be impossible, except among the imbeciles of the race, and that, perhaps, a perfect state of health would be reached when men would be unconscious of themselves. He then recounted the changes which had occurred in the Scottish asylums during the past thirty-five years.

CLASSIFICATION OF DISEASE BY MEANS OF COMPARATIVE NOSOLOGY

was the subject of the address in medicine, by DR. CLIFFORD ALLBUTT, of Leeds. He thought disease should be classified by affinity which should supersede our present system of classification by clinical features. The advances made in comparative nosology, a term rarely heard, have been less than should have been the case.

As the nervous system developes in the higher animals, all diseases must take on a change of type, become more systematic, more complex, more sympathetic with disorder elsewhere; must tend, in a word, to primary or secondary neuroses. The diseases of the lower races of men will differ, and, as a matter of fact, do differ from those of the higher.

In classification by affinity four methods of inquiry must be followed; namely, the hereditary, historical, geographical, and experimental. In the records of hereditary disease we find that observation has been almost wholly directed to the detection of the recurrence of the same form of malady in one family tree; but if we desire a scheme of all the fatal and non-fatal diseases found in the same stock, it cannot be furnished. The inherent tendency of organisms to vary "Nature's bent for inequality," in the words of Matthew Arnold, is well known, if not yet explained.

The historical method leads to the philosophical in all studies, and no less in nosology: unhappily, this study has not yet emerged from the prehistoric period. In the comparison of human disease as it now exists, with its past history, we must remember that in the ruder stages of man morbid variations were constantly eliminated in the struggle for existence. But we begin to see the converse of this condition when human society attained a high degree of development. Natural selection is modified by deliberate counterplots: bad strains are preserved, which, in former times, would have died out. However, bodily improvement may be sought at the cost of the higher mental and effective organizations. Dr. Allbutt gave an interesting *résumé* of racial characteristics in disease. He finds the Dutch rarely the subjects of irritative neuroses; the Scotch, likewise, have a relative rarity of purely nervous diseases, but cancer is more common in Cumberland than in any other of the border counties. Apoplexy and palsy are more common among white than colored people, and among the Germans than the Irish. Among the Indians, diseases of the nervous and circulatory systems are rare, but scrofula and consumption common. The Englishman is patient and courageous under sickness, the Scotchman lies down and gives way under the same conditions, while the Irish Celt is fired with alarm, and magnifies by his vivid imagination both his sickness and recovery. The study of racial peculiarities is intensely interesting, but the variations are known to be manifold: the Arab is not liable to tetanus: the poison of beri-beri does not attack Europeans until they have lived in its district for a length of time: the resistance of negroes to yellow fever is common, as is also their relative immunity from sunstroke and paludal fevers.

In speaking of the geographical method, Dr. Allbutt queried: How have the morbid varieties of man arisen? We can only answer in general terms that we must have especial regard to areas long undisturbed, and, as we must not confound nations with races, we must not confound kingdoms with physiological areas. As in various families, so in various regions, we must work out in each not only the prevalence of disease taken singly, but more especially the schedules of its diseases, noting both coexistence and respective degrees of intensity.

The experimental method will teach us that drugs and poisons will not vary in their clinical effects on living beings by gradual augmentation of differences, but by leaps and bounds, as musical scales respond to scales of vibration. It teaches us that clinical types can be no basis of nosological classification, as we rise higher and higher in the plains of function we enlarge the office of inhibition.

SIR WILLIAM AITKEN, professor of pathology in the Army Medical School at Netly, made the address before the Section on

PATHOLOGY.

Sir William took peculiar gratification in being asked to fill this Chair, on account of his previous connection with Glasgow University. In pathology we have a link which connects us with the science of medicine as distinguished from the art or practice of it; but pathology must be studied as a branch of biology in the widest acceptation of the term; and when medicine was thus thought of as a pure science it implied a "pathology" which had no more necessary subservience to practical ends than zoology or botany. Research is essentially the method of working in pathology. The establishment of the "cell theory" in physiology was swiftly followed by a "cellular pathology" as its logical counterpart. It is unquestionably to Virchow that is owed the great advance by which histology came to take first place as aid to elemental pathology. The direction in which the greatest advances had been made in this section during the present era consisted, (1) in a better appreciation of the "processes of disease," (2) in an increasing importance attached to morbid anatomy, physiology and etiology.

He referred to the introduction of the clinical thermometer, which up to 1864 had no home in England. Even now, with all its usefulness, the theometric observation of disease is but in its infancy, or at least in its youth.

The doctrine of evolution in biology had acquired an importance which he believed especially capable of illustrating the pathology of constitutional diseases.

The doctrine in pathology must be accepted as a part of biology that the laws of variation are ever operative in connection with the origin and development of disease. There are good grounds for believing that new diseases as well as old are in constantly progressive stages of development, although the slowness of their evolution may make us unable to appreciate them.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.[1]

ALBERT N. BLODGETT, M.D., SECRETARY.

MEETING, February 8, 1888.

DR. MORTON PRINCE read a paper on

OPHTHALMOPLEGIA EXTERNA.

DR. O. F. WADSWORTH said: I listened with a good deal of interest to Dr. Prince's paper. I would like to say that, while Hutchinson was the first to propose the name of "ophthalmoplegia externa," and was the first to publish a case in which the nuclei were shown to be the seat of the affection, Graefe presented a series of these cases some ten years earlier. He was at first disposed to consider that there was a tumor; but afterwards gave that up, and supposed some central lesion, although he did not know what it was. I think there have been a number of cases observed besides those which Dr. Prince mentions. The term "ophthalmoplegia externa" was proposed by Hutchinson, and was used by him in contradistinction to another class of cases which he called "ophthalmoplegia interna," in which the internal muscles, the sphincter iridis, and ciliary muscle, and, as he supposed, also the dilatator iridis, were affected only. It is doubtful, perhaps, whether the dilatator was affected in his cases. He referred the latter affection to disease of the ciliary ganglion.

It is interesting to note, however, that although Hutchinson made this distinction in a large proportion of the series of cases that he reported as ophthalmoplegia externa, and in the one case that came to autopsy, where the nuclear affection was demonstrated, the iris and ciliary muscle were affected. Although there are a certain number of cases where only the external muscles are affected without affection of the ciliary muscle and iris, and that condition has remained for a very long time (Graefe stated that he had seen one where for the greater part of the patient's life that condition existed), yet in the large proportion of cases the iris and ciliary muscles become affected, or other cerebral nerves, or nerves of the spinal cord.

Even after the external ophthalmoplegia has existed for a long time without change, other changes have been observed to take place. Then there are certain cases which recover. I reported a case a year or two ago where, with not complete, but partial paralysis of most of the external muscles in both eyes, without affection of the iris and ciliary muscle, and with optic neuritis, the muscles recovered their function entirely. That was a case apparently due to lead poisoning.

It seems to me that the less complicated cases of ophthalmoplegia externa must be considered, most of them at least, as with very little doubt nuclear; unless, as Dr. Prince suggests, we consider that there is a cortical lesion; and we have no knowledge by which at present, we can make cortical localization for the movements of the muscles of the eye. It is very difficult to understand how complete paralysis of those fibres in a nerve-trunk which supply most of the muscles which that nerve goes to can occur, and other nerve fibres, going to other muscles, and running in that trunk, should be entirely unaffected, if the affection is one involving the nerve-trunk; and such cases are those of pure ophthalmoplegia externa. If it was only the oculo-motor that was affected, we might suppose with some probability, that, as has been shown in certain cases, the fibres of the ciliary muscle and iris run through the abducens; but when the abducens as well as the oculo-motor, or the muscle supplied by the abducens as well as the muscles supplied by the oculo-motor are affected, this explanation would not be valid.

Some of the cases with complete paralysis of most of the ocular muscles show immunity of other muscles besides those of the iris and ciliary body which are supplied by the same nerve. For instance, I showed at the Improvement Society, some eight or ten years ago, a man with locomotor ataxia, who had complete paralysis of all the muscles supplied by the oculo-motor, and that on both sides, including the iris and ciliary muscle, except the muscles that raised the upper lid. These latter muscles on both sides were unimpaired, apparently, in their function. At that time I was not familiar with the nuclear affections, but I think now that there can be little doubt that there was in that case an affection of the nuclei; I cannot understand how all the other fibres should have been completely paralyzed and the fibres going to the levators unaffected, unless the trouble were at a spot behind the place where the fibres become joined.

I should like to mention one other case where the ophthalmoplegia externa was complicated with other affections. It was a young man from Keene, N. H., whom I saw four or five years ago, who fell while getting from a sleigh, striking on the back of his head. He went home without assistance. He soon had double vision and dizziness (probably in consequence of the double vision), persistent headache and vomiting. He was somewhat somnolent and there was some mental impairment. At the time I saw him there was paralysis of a number of the muscles of both eyes, muscles supplied by different nerves. He finally died, and Dr. Bridgman sent me a report of the autopsy, in which were found a number of spots of softening, chiefly in the region of the pons but also in one or two other places in the brain. My probable diagnosis had been tumor in the region of the pons, and it is quite possible, I think, in the absence of microscopic examination, that the spots of softening were due to broken-down glioma. I have never myself seen a case of pure ophthalmoplegia externa that lasted for any length of time under observation.

I cannot give all the references, but I think there have been a number of cases in which the nuclei or parts in their immediate neighborhood were shown to be diseased, and where ophthalmoplegia had existed together with other symptoms.

DR. J. J. PUTNAM: I will detain the Society but a moment. I think this class of cases is one of extreme interest. We find that the third nerve is not a single organ, but that many nerve cells lie side by side which have different functions and different susceptibilities.

[1] Concluded from Vol. cxviii, page 431.

Furthermore, the fibres which make up the nerve do not all come from the same nucleus. Take, for example, those fibres of the third pair, which raise the upper lid. A portion of them seem without question to come from groups which lie lower down than the primary nucleus to which Dr. Prince has alluded.

It is difficult to criticise or say very much about a paper like Dr. Prince's, which one would need to examine previously in detail. This I hope we shall have the opportunity of doing in print. I will simply add what little I have to say which seems to throw any light upon the subject. I have seen a number of cases of this sort, none of them perhaps pure cases. It seems to me sufficiently evident from what has been said that the pure cases of paralysis of all the external muscles of the eye, without implication of any of the internal muscles, and without any symptoms which would indicate that other portions of the nervous tissues were affected, are very rare, although they certainly do seem to exist, and the patients carry the symptoms, as has been said, through life occasionally, certainly for very long periods.

One point of etiology seems to be interesting out of many interesting points. As Dr. Prince said, I think the original cases reported by Hutchinson were supposed to be of syphilitic origin, and this group of symptoms has rather borne the stigma of syphilis on it that seems to be undeserved. A number of cases have been reported as following diphtheria, and that, it seems to me, opens an etiology of great practical importance. These diphtheritic cases are probably cases of multiple neuritis, of which we have heard so much of late. Of that same origin, as I believe, was a case of partial oculo-paralysis with other symptoms pointing to lead poisoning, which I have had an opportunity to observe during the past year, and various other cases which have been reported from time to time. In fact, in quite a number of cases of multiple neuritis, reference has been made to paralysis, partial or complete, of various ocular muscles. A case has been recently reported also, where both facial nerves were diseased.

I have also seen within the past year a patient exhibiting partial paralysis of all the external muscles of both eyes, with almost complete, if not complete preservation of accommodation. The rest of the muscular system was not paralyzed, but became very weak, so that she arose from her chair with difficulty and came to my office attended by a friend, and she had sensory symptoms such as one sees in cases of multiple neuritis of moderate severity. These symptoms gradually improved I think, during the time that I had an opportunity of observing the case, six months or more, but they had by no means passed away, and the case had already lasted some months before I saw it. She told me, moreover, that she had had a similar attack some two or three years before, of shorter duration. It seems to me impossible that we should assume, in such a case as this, that the various processes were of central origin. It seems to me more probable that the whole group of symptoms were due to multiple neuritis, and so I think with some of the other cases.

I have also recently had an opportunity to see an exceedingly interesting case which may have been one, possibly, of hæmorrhage into the pons; at any rate, where the muscles of the eye, external and internal, were involved.

There is one other point in reference to what Dr. Wadsworth has said. It is difficult to see how a portion of a nerve can be pressed upon without the rest of the nerve being involved. Referring again to the case which Dr. Prince mentioned where the only paralysis spoken of during life, I think absolutely the only one, was the loss of movement upward, and where a gummatous tumor was found destroying both of the third nerves in their passage from the crus cerebri; it seems to me that this paralysis upward is observed much more often and much more fully than the loss of lateral motion. At any rate, I have seen recently two cases, one of them in a patient whom I saw to-day at the hospital, where both of the third nerves were affected and no other nerves apparently, but in both cases, and particularly in the one that I saw to-day, although the lateral motions are now present to a very considerable degree, there is entire loss, so far as I could see, of motion either upward or downward.

DR. P. C. KNAPP said: I have listened with a great deal of interest to the paper of Dr. Prince, because I think that the whole subject of ophthalmoplegia externa and the question of disease of the nuclei in the bulb is of very great interest, as filling up the gap in our knowledge of the diseases of the motor tract, especially in its relations to the other diseases of the motor tract lower down, such as progressive muscular atrophy and bulbar paralysis proper.

It seems to me, too, that these cases can be brought into more or less relation with the diseases of the motor tract lower down. We know that in affections involving the limbs, for instance, we may have disease in the cortex itself; in the pyramidal tract, especially the internal capsule; in the anterior cells of the cord; in the nerve-fibre; or in the muscle itself. Unfortunately, in the muscles of the eye, we cannot test the electrical reaction, whereas in the arm we can say definitely by the change in the reaction whether the disease is on one side or the other of the motor cells in the cord. In the case that Dr. Prince has spoken of, where there was no disease whatever to be found in the bulb or in the oculo-motor nerves, it is possible, as Oppenheim and Siemerling have suggested in a paper on pseudo-bulbar paralysis,[2] that there is a lesion, not in the capsule, but in the centre for the eye, wherever that may be — possibly in the angular gyrus.

We know, too, that disease in the nuclei will cause this paralysis, and, furthermore, we know that there is in all probability a peripheral disease — we get it in certain isolated muscles in syphilitic disease — where it has absolutely been found that there is a lesion of the nerve after it leaves the motor cell, just as we get a neuritis elsewhere. As far as I know, however, there is not a definite acute inflammatory affection in the bulb, or, at least, in the particular nuclei in the bulb, corresponding precisely to the acute inflammations in the cord. There are, however, a good many affections which may produce this paralysis. In the first place, there are many tumors which may destroy these cells — just as in the cord we may find tumors and other processes which will lead to the same paralyses which, in some cases, resemble progressive muscular atrophy; and so these nuclei in the bulb may be destroyed by tumors or hæmorrhagic encephalitis. Moreover, disease in the floor of the fourth ventricle may destroy them by extension. Nor did I mean to imply that Erb's scheme was to be re-

[2] Berlin Klin. Wochenschr., 15 Nov., 1886.

garded as absolute, that the individual nerves could not be spared in the case of such a lesion. I certainly intended to make the exception that, in post-diphtheritic cases, for instance, where there was in all probability a neuritis, and in many other cases, you could get an involvement of the tissues of the nerves without involving the other structures. As Dr. Putnam has suggested in a recent paper on alcoholic neuritis by Witkowski,[3] it was found that the terminal branches of the nerves were first and most extensively involved. It would be explanatory of some of these cases where there was no affection of the internal muscles of the eye. They may be due, possibly, to the neuritis.

Dr. Wadsworth: May I add only one word? If we have a partial paralysis of some of the muscles supplied by the third pair, while the iris and ciliary muscle are unaffected, of course it is perfectly possible that that should be peripheral. In a considerable proportion of the cases of paralysis of the muscles supplied by the third pair we have such partial cases, and it is generally agreed to consider most of these cases as peripheral; but that is quite different from the case where there is complete paralysis of all the muscles, except the ciliary muscle and iris.

Dr. Prince: I would like, in conclusion, to say one word, especially in regard to paralysis due to peripheral affections. If I understand Dr. Wadsworth, I think experience shows the opposite from what he contends. It is an every-day experience to see paralysis of some of the fibres of nerves without the remaining fibres being affected. We frequently find in peripheral neuritis some of the muscles supplied by the nerve affected, and others not. We find it frequently the case in disease of the facial nerve. It is common experience that, even with intense inflammatory affections, all the muscles are not equally affected.

In one of the cases referred to in my paper, we have a demonstrated case, with autopsy, where there was, on one side, almost complete degeneration of one of the nerves, while the nerve on the other side was only partially so, and yet on both sides nearly the same muscles were affected, and no more in the one side than in the other, and the iris and sphincter were not affected. Also, we have cases following diphtheria, where there were also other symptoms pointing to peripheral disseminated neuritis, there was loss of knee-jerk, etc., ending in recovery. There was another case with no paralysis, but only anæsthesia, followed by recovery. This is experience. I don't mean to argue in favor of the peripheral nature of these affections. It is often difficult to make the diagnosis. In my case I cannot make a diagnosis, but I think that the view must be given up that the disease necessarily means nuclear affection. In regard to the inclusion of the other cases in this category, as Hutchinson did, where there is also paralysis of the ciliary muscle and the iris, of course every one knows that you can have that lesion with paralysis of all the muscles of the third nerve.

There is another case where there was only right-sided ophthalmoplegia externa, and where there was a softened portion extending the whole length of the brain-stem from the thalamus to the pons.

Dr. Wadsworth: It seems to me that we ought to distinguish between the cases of pure ophthalmoplegia externa, which Hutchinson departed from as soon as he had given the name, and cases complicated by other nerve symptoms. In the cases of pure ophthalmoplegia externa, where the iris and ciliary muscle are not affected, and there are affections of the ocular muscles belonging to both eyes and more than one nerve, in such cases it seems to me we have a right to suppose nuclear lesion without going farther. If the iris and ciliary body are affected also, then we have to consider all the circumstances of the case: what muscles are affected, what other symptoms may be present. Of course, there can be no question that we may have multiple paralysis of the ocular muscles from peripheral causes, but that we can have peripheral causes which shall pick out all the fibres in a nerve-trunk which supply certain muscles, quench their function entirely, and leave the fibres in the same trunk supplying other muscles intact, I doubt. The experiments of Heusen and Voelckers on rabbits show, so far as physiological experiments can be relied upon, that, in them, at least, the centres for iris and ciliary muscle are farther forward than the centres of the other muscles supplied by the third pair; and there are pathological and anatomical cases which point in the same direction in man. So it is easy to understand how some nuclei are affected, and not others. I should say that multiple neuritis does not seem to present the pure cases of this disease.

Dr. Putnam: I cannot entirely agree with Dr. Wadsworth. It seems to me that we do find the fibres of a single nerve picked out, as in cases of peripheral neuritis, where the whole system of motor fibres is sometimes degenerated, with entire destruction of the muscles which are attached, and yet the sensory fibres are not involved to any very considerable degree. Furthermore, any one who has examined the nerves of the acute degenerative cases which occasionally occur will have been struck by the fact that side by side with the fibres which are seriously involved are other fibres which are apparently entirely healthy. It is not necessary to suppose that of the fibres lying side by side some only are affected; the disease sometimes begins at the periphery and spreads inward. It is in this way that ataxia is sometimes observed without any corresponding degree of cutaneous anæsthesia, the fibres coming from the muscles being affected out of proportion to the fibres coming from the skin. And where a cranial fossa is the seat of exudation, as I understand Dr. Knapp to assume, I think that there, also, it is admitted that the nerves may be involved in the most singular manner; some of them being entirely unaffected, and others partially affected.

Dr. Knapp: I am afraid that I did not make myself quite as clear as I would like to have done to Dr. Putnam. I meant that, except in the cases of peripheral neuritis, where the nerve-fibres could be affected independently of any surrounding tissue, this statement of Erb might hold true, that the other nerves in the neighborhood might be affected. I do not mean to imply that there may not be cases where the individual nerves are involved; again fasciculated sclerosis or multiple sclerosis may pass up into the nuclei; and, finally, there probably may be, as shown by autopsy in Westphal's case, a degeneration of these special cells precisely similar to the degeneration of the cells in progressive muscular atrophy or in bulbar paralysis. There are probably two classes of these cases of nuclear disease: those where the affection is accompanied with symptoms of tabes, and those where it is an isolated disease, or with other degenerative process

[3] Archiv. f. Psych. u. Nervenkrankheiten, xviii, 809, 1887.

in the motor tract, the true progressive bulbar paralysis, and progressive muscular atrophy.

The acute form of polioencephalitis generally comes on in apoplectiform manner, and is attended with a certain amount of paralysis of the limbs. The differential diagnosis between the cortical and nuclear form and the form from peripheral neuritis is, of course, not easy. Neither is it always easy to differentiate it from some possible lesion higher up, or from pseudo-bulbar paralysis; at the same time, there are certain points which may be considered, which will, at any rate, help in the diagnosis between the peripheral and the nuclear forms.

In the first place, where only a single one of the ocular muscles is paralyzed, it is, I think, rather more likely to be peripheral than to be nuclear. Where a good many muscles are paralyzed, we must bear in mind another point brought forward by Erb: In the first place, to produce complete ophthalmoplegia, there, of course, must be a paralysis of the three nerves, the oculo-motor itself, the trochlear, and the abducens. Now, a peripheral lesion which involves all these three nerves, excepting, possibly, the post-diphtheritic neuritis, which may pick out the nerves themselves, without the surrounding tissue, would also involve the fibres for the internal muscles of the eye in the third nerve; and, if it were in the orbit, we should expect that the upper branch of the fifth nerve, and also the optic nerve, would be involved. We would thus get optic neuritis, neuralgia, and anæsthesia of the upper portion of the fifth, etc.

In the fossa of the skull, however, we have a different state of things. Disease which would be sufficiently extensive to take in the fifth, sixth, and fourth nerves in the middle fossa of the skull, which comes up to the upper portion of the pons, must in all probability take in the whole of the fifth, so that we should find affection of all the branches of the fifth nerve; whereas disease farther back, sufficient to take in the sixth, and also the third and fourth, would probably take in the fifth, and with it the seventh and eighth, so there would be affection of the other motor nerves.

One more point, in regard to the suggestion of syphilis. I would say that the first case that Dr. Prince reported I saw a good many times last winter, when I took the service, and she had been given iodide of potassium then. It was pushed until she took somewhere between two or three drachms three times a day, without any effect, and therefore, it must have been in this nucleus that I speak of, and from a negative point must have considerable bearing.

There is another way in which we may consider that we have a peripheral neuritis in which we may notice ophthalmoplegia externa. The third nerve first divides, sending a branch to the external rectus. This branch then sends a short branch to the ciliary ganglion, and after that goes on and supplies the other muscles of the eye. From the ciliary ganglion run the ciliary fibres to the ciliary muscle. You simply have to suppose, in that case, a neuritis affecting the terminal filaments either before or after the fibres going to the ciliary ganglion, without involving the ciliary muscle. That is a possibility that has been considered in the autopsies. In one case, I believe, it was not found.

The PRESIDENT appointed as a Committee to take into consideration the address from the College of Physicians, Drs. Barnes, Folsom, and Durgin.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 30, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

THE SCIENTIFIC SPIRIT OF THE AGE.

UNDER this head, Frances Power Cobbe, a strong-minded English lady who has been chiefly noted the past few years for her ravings against vivisection and experiments on animals, which, she thinks, exercise a "demoralizing influence upon any person who may be called upon to make them," writes in the July *Contemporary Review*. She deplores the "materializing tendency of a scientific education," which, among other evils, fosters a "callous and irreverent spirit." "Disease," as estimated from a scientific standpoint, "is the most important of facts and the greatest of evils. Sin, on the other hand, is a thing on which neither microscope nor spectroscope, nor even stethoscope, can afford instruction." The Scientific Spirit (the capitals are hers) is at war with religion, which now "meekly goes to church by a path over which Science has notified: 'On sufferance only!'" We are in danger of losing the pleasures afforded by Art and Nature, Poetry and Music, as fast and as far as we become pervaded by the Scientific Spirit, and the question is pathetically asked: "What shall it profit a man if he find the origin of species, and know exactly how earth-worms and sun-dews comport themselves, if all the while he grow blind to the loveliness of Nature, deaf to music, insensible to poetry, and as unable to lift his soul to the Divine and Eternal as were the primeval apes from whom he has descended."

All this indictment is sufficiently dreadful, if true, although in substantiation of it the writer produces only one witness, the late Mr. Darwin, who, in his recent autobiography, avows that the ever-increasing devotion to the special scientific studies which had absorbed the energies of his life had destroyed his relish for poetry, music, and art. Mr. Darwin was in this respect an exemplification of what every man experiences to a greater or less degree who concentrates his powers on any one study for which he has a special aptitude. It is not necessarily scientific men who, by devotion to their particular calling, becoming in a measure incapable of æsthetic enjoyments, are ex-

amples of what every one knows to be a physiological law, and of which Miss Cobbe might have found another striking instance in Sir Isaac Newton, who was, however, a very religious man; it is just as true that persons with an extraordinary penchant for *music* are often deficient in the scientific spirit, or, to use Miss Cobbe's metaphors, blind to the beauties of science and deaf to the harmonies of nature. The same may be be said of a natural fondness for any of the arts which may produce in the individual a one-sided development. It is, moreover, a fact that, by virtue of the physiological law, true greatness in any specialty becomes possible by the localization and concentration of energy.

That earnest and eminent workers in science may, however, have a cultivated taste for and take a genuine delight in æsthetics, can be affirmed with thousands of examples to support the assertion, and very many of the scientific readers of Miss Cobbe's article will indignantly resent the imputation that scientific habits of thought are in any way inimical to or destructive of the religious sentiment. It might even be contended, to the contrary, that an intelligent appreciation of the order of nature — in the minutest things, as in the greatest — must tend to foster a reverent and devotional spirit, and render a person religious in the true sense of the word.

It cannot be too much insisted on that, whatever apprehensions may be entertained as to the possibilities of harm to cherished beliefs from the prevalence of the scientific method, science is simply *the knowledge and application of facts* (in the moral, as well as in the physical universe), and that any system or belief which can be shown not to be based on facts is pernicious, and ought to be destroyed. Nor can aught but good result from the diffusion of scientific facts and principles, for there can be nothing better or more worthy of pursuit than truth, which is the subject-matter of science.

There is one point in connection with Miss Cobbe's *Contemporary Review* article where there will be more sympathy with the writer among the readers of medical journals; namely, her animadversion of a peculiarly modern custom pertaining to the publication by secular papers of details respecting the sickness and death of certain distinguished patients, though her apparent hatred for doctors leads her to statements that few of our readers will exactly endorse.

"The political press has adopted the practice of reporting the details of illness of every eminent man who falls into the hands of the doctors, and affords these gentlemen an opportunity of advertising themselves as his advisers. The last recollection which the present generation will retain of many an illustrious statesman, poet, or soldier will not be that he died like a hero or saint, bravely and piously, but that he swallowed such and such a medicine, and, perhaps, was sick in his stomach. Death-beds are desecrated that doctors may be puffed and public inquisitiveness assuaged." If doctors do advertise themselves as Miss Cobbe boldly asserts, there is something to be said on the other side. The doctor who dares refuse information about a distinguished patient, has before now been made the subject of criticisms, almost as unpleasant as those of Miss Cobbe herself.

THE BREEDING OF PAUPERS AND CRIMINALS.

At the recent Prison Congress, Mr. C. H. Reeve, of Plymouth, Ind., read a suggestive paper on "Dependent Children," which went deeper than the very obvious question of their support and rearing. In regard to the existing conditions, he said that the origin of a majority of the most undesirable of these children exists in an erroneous and perverted view, by both State and Church, of what constitutes a true marriage, producing a vicious civil and canonical legislation that encourages and sanctions their production, thereby constantly widening the planes of pauperism and crime.

"The mass of dependent children is largely made up of foundlings, illegitimates, children abandoned by worthless parents, orphans of the very poor, with a few better born who become waifs from various causes. In the cases of nearly all of them except the last there is more or less mental deficiency, or deformity in the brain substance, or the conformation or arrangement of brain ganglia.

"Statute law makes marriage a civil contract — a matter of dollars and cents. No matter who comes for a marriage permit — the strong or the weak-minded, the sound and healthy or the deformed and constitutionally diseased, the millionaire or the hereditary pauper, the moral and orderly or the vicious and confirmed criminal, the progenitor of statesmen or of idiots, the sane, or the hereditary insane if favored with a lucid interval, the temperate or the besotted — all are given a permit alike. The revenue is collected, the ceremony authorized, the record made, and this civil contract is fully completed by sanction of law! If a man wants to run a locomotive engine, or practice medicine (elsewhere than in the United States) or plead in the courts, or stand in the sacred desk and talk theology, or teach a school, or run a pilot boat, or even to secure a petty clerkship under Government, he must submit to a rigid examination as to his fitness for the position and its duties, and be able to pass one. But one comes forward to get a permit to enter into a contract that places him under obligations and demands of him duties that are the most important, the most responsible, the most sacred that can be assumed anywhere between the cradle and the grave, that vitally affect the bodies social and politic as well as corporal, now existing and hereafter to exist, directly and indirectly, not a word is said. All are licensed."

Not very long ago the public was admonished by a consul of the United States that a lawful marriage in the United States was not necessarily binding in France as between a Frenchman and an American. It

seemed shocking, but looking at our marriage system as here presented, there is certainly much to be said for the French views of the subject.

Mr. Reeve does not consider the church blameless in the matter. "It regards marriage as a holy, sacramental covenant. By permission of law its ministers ceremonially aid the parties in making this holy covenant, which, at the same time involves the statutory civil contract. It makes little or no inquiry as to the candidates. (One organization may as to belief in a creed). It looks only for a license and the fee in prospect. Even in the shadow of the prison wall and of the gallows its ministers, in sacredotal robes, have united criminals. Thus is it *sanctioned by the church!* What a shocking view is before and around us when we see the public opinion, both legal and social, upholding these conditions! Government maintains a bureau and employs scientific experts, regardless of expense, to hunt out and kill diseased horses and cattle; invades anybody's premises for the purpose, and makes it a crime for the owner to resist. But when a viciously diseased man or woman applies for a legal permission to taint whole generations it asks no questions, extends no protection for individuals or the public, but grants the permit.

"What must follow and does follow this universal misuse and abuse of knowledge and liberty? Plainly, the constant and rapid peopling of the planes of pauperism, idiocy and crime, and the steady widening of those planes; physical and mental disease and deformity; the evolution of new forces that pervert the correct views of a true humanity, and tend to destroy moral perception."

Mr. Reeve made certain suggestions concerning the care of these little unfortunates, and then went on to say that "with the statutes providing for homes and training schools, there should be others looking to the prevention of pauperism and crime by preventing the production of paupers and criminals, and especially their production under the permission and sanction of the State laws and social usages.

"It is a greater evil to bring into life a child on the plane of hereditary pauperism, or in the line of successive criminals, than it would be to adopt the theory of Malthus, confining it to those planes. There is as much wrong in bringing into life a child with insane parentage as there would be in driving a sane child insane by cruel and brutal usage. There is more wrong in bringing into life a child without legitimate parentage than there is in child-stealing for the purpose of professional beggary.

"Let us hope that, slowly, but surely, the knowledge will obtain that marriage is not romance, but the very highest order of business, requiring more deliberation, more care and forethought, and entailing more responsibility than any other act known to humanity. That Government will recognize that it has no greater obligation resting upon it than to see that none have its license to enter into a contract of marriage who are unfit for its relations and duties, as far as human foresight and legal provisions can prevent, and proper inquiry can prevent in most cases, if it be aided by sufficient penalties."

It is a hopeful view of the power of law to suppose it can so regulate the marriage relation as to put an end to the breeding of criminals, paupers, and insane. Careful regulation of marriage has not been so successful in countries where the regulations are most strict as to warrant any very great reliance on it; and surely it would be a curious condition of affairs to forbid the rearing of criminals at home while we import them so freely from the old world, but the condition described in the article we have so freely quoted is one that deserves recognition, and if laws can but imperfectly control the matter, such statements will certainly help to awaken public knowledge upon the subject. Newspaper reports tend to show that Dr. Richardson's chapter on the "Intermarriage of Disease" has brought him a considerable amount of correspondence from those who desire to apply to their own cases what he has to say on the subject.

MEDICAL NOTES.

— A writer in the *Popular Science Monthly*, commenting on the various theories advanced for the prevalence of baldness, says, that while a resident of India he had an opportunity of extended observation of the Parsees, who are compelled by law and usage always to keep the head covered. Through the day they wear a high hat without a brim, which is always made very tight to keep it on, creasing the scalp and he thinks possibly the skull, by its constricted rim; when they remove this, they substitute a skull-cap. But he has never seen a case of baldness in them, nor have they themselves been able to report one to him among their own race. This fact seems to have a rather a damaging effect on the tight-hat-band and constant-hat-wearing theories of baldness.

NEW YORK.

— Among the passengers on board the steamship *Trave*, which arrived from Bremen on the 24th of August, were the eminent German surgeon, Prof. F. E. August von Esmarch and his wife, the Princess Henrietta of Schleswig-Holstein, a cousin of the present Empress of Germany. They were accompanied by their son, Dr. Erwin von Esmarch. The distinguished visitors were met by friends down the bay and escorted to the apartments of Dr. F. Langé, on Lexington Avenue. It is their intention to see as much as possible of America on this, their first visit to the country, and they will devote their time principally to travel and pleasure, though Professor von Esmarch will attend the Medical and Surgical Congress at Washington in September. He is now in his sixty-fifth year, while his wife is fifty-five years old. The Princess is the daughter of Prince Christian, the brother of the German Empress's father, Duke Ernst Gunther.

— Mrs. R. H. Townsend, who, last year, erected at her own expense at Bellevue Hospital a pavilion for operative procedures on female patients, has now given to the Hospital a brick building, two stories in height, for a library and chapel. It is located on First Avenue, immediately in front of the main hospital building, and, when completed, it will conform in general style to the surgical pavilion referred to, which stands on the Hospital grounds at the corner of First Avenue and 26th Street. Heretofore the patients' reading-room has been the office of the Medical Board, and the amphitheatre where the general clinics are held the only place in the institution that could be used as a chapel.

— The Quarantine Commissioners have adopted a resolution in which, in accordance with the power vested in them by an act passed by the last State Legislature, they make Cape Henlopen, instead of Cape Henry, the northern point for quarantine inspection.

Miscellany.

MACTE LISTER TRIUMPHATOR![1]

A Moist-merry, Humid-hilarious Antiseptic Vade-mecum of Internal Surgery, for the Ambitious Modern Physician.

By Dr. Risorius Santorini. Translated by "Famulus."

All Rights Reserved. 1888.

(c) *Pulmonary Resection.*

What I have heretofore recorded
Of treatment in conditions morbid
Is prudence, care, conservatism;
Is surgical asceticism,—
Is like amœbic protoplasm
Compared to perfect organism,—
Is modesty, fear, vacillation,
Timidity, procrastination,—
Like infant birth to resurrection,—
Has with true courage no connection,
When we consider lung-resection.

"Experimentally" it 's stated
That normal lungs when amputated,
"Usually" bear this grave proceeding
With little shock and moderate bleeding; —
But even with this full explanation,
I would not risk the operation.

It must be that some detail hitches,
When, of eight strong and healthy bitches
Subjected to this mutilation,
But three survived the operation.

Herr Dr. Schmidt calls this "success:"
I might esteem it something less.

But Dr. Block is my example,
Who after toils and trials ample
With all the various lung-insults,
Reported that he got "results,"
With dogs and oxen, cow and pig,
Hares, rabbits, creatures small and big;
A large and pitiful collection
All sacrificed to lung-resection.

[1] Continued from page 190.

A score recovered — stop! I pray!
I 'll put a question, if I may
[Correct statistics is my pride],
How many of the creatures died?

Ah! would some fairy realistic,
Might sometimes alter facts statistic.

Herr Ruggi, spite of diagnosis,
Resected even tuberculosis.
The patient, through perversity,
Died the same day quite suddenly.

Therefore, observe this one direction
Whene 'er you meditate resection;
Tuberculous lung, where 'er it be,
Is not subject to surgery.

At the same time —Krœnlein has proved it —
(Costal sarcoma — he removed it —)
If to our skilful apprehension
There should be visceral extension;
If the disease should penetrate,
And in the lung proliferate;
If from contact there be a nodule
In peripheric lobe or lobule;
Indulge no further hesitation
Resection is the one salvation.

Therefore, take due care I pray,
Before lung-surgery you essay,
These points you strictly should observe:
Let not your operative "nerve"
Deprive each case of careful study
Before an operation bloody.

Determine, first, if there's adhesion
Between the pleura and the lesion.
For this, an acupressure stylet
(Though doctors often new revile it)
Affords the means of information.
If in the act of respiration
No rhythmic-movement is detected,
A fatal end must be expected.

This is pulmonic surgery.
If you employ it bold and free,
'T will advertise you far and wide;
You'll be extolled on every side.

But I entreat you earnestly
To hold yourself from humbug free;
Which Cayley did not hesitate
With his real worth to associate;
Who maintained in a "genial" thesis
The ground that profuse hæmoptysis
May be relieved, — yes, cured, perhaps
If we the bleeding lung collapse
By operative pneumothorax!!
This might be well in Corvus corax.
This method he, in fact applied;—
The patient very promptly died!

CHAPTER III.

CARDIAC SURGERY.

(a) *Paracentesis Pericardii.*

With weird and superstitious fears
The pericardium appears
For ages to have been neglected
Nor once *in vitam* well inspected.

Few had the courage even to try
Paracentecis pericardii.
Surgery shrank with terror back
When near the pericardial sac.
But nowadays we read and hear
Of various cases every year.
But in *one* man all arts combine,
His name is Dr. Rosenstein.

In the fourth intercostal space
(Exact percussion shows the place),
A finger's breadth from sternal edge,
He punctured, and with "Ego sum"
Pumped from the pericardium,
By means of Potain's instrument,
The sero-purulent content.

But he received no recognition
Till later he made free incision;
An opening wide he then maintained,
And thus the pericardium drained.

Alas! it's easier in our day,
This to describe than to essay!
Who therefore would upbraid a fellow,
Or fancy that his skull were callow,
If rarely he should find occasion
For such a doubtful operation?
Ah! could we gather information
In each case of the exudation,
We should feel much more certainty
In pericardial surgery.

But as the symptoms may agree
With those of heart-hypertrophy;
As well as cardiac dilatation
Due to defective compensation —
Not to allude to aneurism —
Alas! This is no solecism.
If any case in judgment tax him,
The doctor should apply this maxim;
To advocate no operation
Before sub-dermic exploration.

Given, that to a great degree
And permanently there's dyspnoie,
The law is: Promptly operate.
The heart else may degenerate;
And bacillary immigration
Occur within the exudation.

(b) *Cardicentesis.*

Behold to what sublime degree
Now towers internal surgery!
And possibly your lips proclaim
Of German intellect the fame.
But in America you'll find
We leave the Germans far behind.
Have you not heard of Westbrook's name?
Do you not know of Westbrook's fame?
Who, when heart-failure with aphonia
Appeared in course of a pneumonia,
The right auricle aspirated,
And ninety grammes of blood vacated.
The next day, punctually at three,
Was held the patient's autopsy.
The cavum pericardii
Was filled with blood and flocculi;

But Roberts hopes "with certainty"
That in a few years we shall see
Good doctors all with acclimation
Adopting Westbrook's operation.

My friend, you should not feel surprise
At anything a Yankee tries.
From him we soon expect direction
Not only for cardiac resection,
But for aortic ligature.

(To be continued.)

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

WASHINGTON, D. C., August 27th, 1888.

In view of the fact that frequent inquiries are made of the Committee of Arrangements by medical men and others in regard to the character of the organization now known as The Congress of American Physicians and Surgeons, which will hold its first triennial session in Washington, September 18, 19 and 20, it may be proper to state that several years ago the American Surgical Association, passed a series of resolutions declaring it expedient that the special medical societies in this country should adopt some plan of organization by which they should be brought together at certain stated periods, and invited the other societies, to co-operate with it in perfecting such a scheme. This invitation was accepted by the several societies, and in October, 1887, a committee of conference, composed of delegates from each of the societies, assembled in this city and agreed upon a plan of association, which was subsequently considered and accepted by the societies constituting the Congress as now organized. This plan consists simply of the agreement that the medical societies named shall hold their usual annual meetings at the same time in this city every third year, and that an executive committee, composed of one member of each society accepting the agreement, shall arrange for one or more general meetings for the consideration of such medical subjects, by such physicians and surgeons as it may select, to be followed by such general discussion as time may permit. The present Executive Committee is also charged with the duty of devising and submitting a plan of permanent organization, which will be considered at a preliminary meeting on Tuesday morning, September 18. There is no membership in the Congress proper. Membership belongs exclusively to the several societies constituting the Congress. Each society prescribes it rules for admission of candidates, and transacts its business according to its own method. The Congress, as such, does not in any manner interfere with the autonomy of the several constituent societies.

The guests are men of distinction in some special department of Medical Science, who have been invited by some one of the constituent societies to attend its meetings, and perhaps to present a paper on some chosen subject. They are guests of a society, not of individual members. The Committee of Arrangements has not claimed or exercised the privilege of naming guests, nor has it conceded the privilege to individual members. At its suggestion the Executive Committee has invited the heads of the government bureaux of medicine, the president of the last International Congress, and several citizens to whom it was indebted for courtesies. In the event there should be present from abroad any medical man, who may not have been specially invited, the Committee will hold itself bound by ordinary courtesy to include him in the list of guests.

The meetings of the Congress and of the Societies will be open to the profession. Any medical man who may choose to attend has the privilege of doing so; but the privilege of taking part in the discussions will be limited to the members, guests, and those who may be invited to do so by the societies respectively. The invitation to attend the meetings and engage in discussion will not, however, entitle one to the privileges of a guest.

Members and visitors must avail themselves of the ordinary excursion rates of railroad fare.

The Postmaster of this city has arranged facilities for the distribution of the mail at the office of registration, in Willard's Hotel. Letters must be addressed to "The Congress of American Physicians and Surgeons."

It may be added that the Committee of Arrangements declines to make any provision for, or to have anything to do with, any exhibit of pharmaceutical preparations and medical and surgical appliances.

I assume the responsibility of making the foregoing statement for the information of those concerned, and to avoid confusion and misunderstanding. And it gives me great pleasure to announce that the meeting in every aspect promises to be a conspicuous success. Yours truly,

SAMUEL C. BUSEY, M.D.,
Chairman Committee of Arrangements.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 18, 1888.

Cities.	Estimated Population for 1888.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 3,079: under five years of age 1,527; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,067, consumption 295, acute lung diseases 130, diarrhœal diseases 751, diphtheria and croup 112, whooping-cough 61, typhoid fever 55, malarial fever 32, measles 25, scarlet fever 16, erysipelas eight, cerebro-spinal meningitis seven. From whooping-cough, New York 24, Baltimore and Washington five each, Brooklyn eight, Chicago and St. Louis four each, Boston and Pittsburgh three each, New Orleans and Cambridge two each, Charleston one. From malarial fevers Brooklyn eight, St. Louis six, Baltimore five, New York and Washington four each, Charleston two, New Orleans, New Haven and Nashville one each. From measles New York 13, Chicago eight, Brooklyn two, Pittsburgh and New Haven one each. From scarlet fever New York eight, Brooklyn five, Boston, New Orleans and Pittsburgh one each. From erysipelas, Boston four, New York, Chicago, St. Louis and Worcester one each. From cerebro-spinal meningitis, New York three, Boston, Nashville, Worcester and Lynn one each.

In the 28 greater towns of England and Wales with an estimated population of 9,398, 273 for the week ending July 28th the death-rate was 15.8. Deaths reported —: Infants under one year —: acute diseases of the respiratory organs (London) 160, diarrhœa 156, whooping-cough 65, measles 62, scarlet fever 40, diphtheria 35, small-pox (Preston) 3.

The death-rates ranged from 8.1 in Derby to 25.4 in Halifax: Birmingham 13.2; Bradford 12.7; Hull 14.4; Leeds 16.6; Leicester 12.4; Liverpool 17.1; London 15.9; Manchester 20.3; Nottingham 12.0; Sheffield 15.9; Sunderland 15.8; Wolverhampton 16.0.

In Edinburgh 13.7; Glasgow 17.0; Dublin 18.0.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending August 4th the death-rate was 16.0. Deaths reported 2,881: Infants under one year 898; acute diseases of the respiratory organs (London) 167, diarrhœa 215, measles 64, whooping-cough 61, scarlet fever 39, diphtheria 27, fever 21, small-pox (Preston two, Sheffield, Hull and Oldham one each,) 5.

The death-rates ranged from 21.9 in Manchester to 9.0 in Bristol: Birmingham 15.8; Bradford 13.6; Leeds 16.5; Leicester 18.1; Liverpool 18.6; London 15.9; Nottingham 12.7; Portsmouth 14.6; Sheffield 18.8; Sunderland 13.4.

In Edinburgh 15.7; Glasgow 18.2; Dublin 21.1.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING AUGUST 25, 1888.

Simons, Manly H., surgeon. Detached from "Constellation" and to the Naval Academy.

Russell, A. C. H., passed assistant surgeon. Detached from "Constellation" and to the Naval Academy.

Dickson, S. H., passed assistant surgeon. Detached from Marine Barracks, Washington, D. C., and to the United States Steamship "Richmond."

Cordeiro, F. J. B., passed assistant surgeon. Ordered to the United States Steamship "Mohican."

Farwell, W. G., surgeon. Detached from the United States Steamship "Saratoga" and ordered home to wait orders.

Dickinson, Dwight, surgeon. Detached from the United States Steamship "Portsmouth" ordered home to wait orders.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. A., FOR THE WEEK ENDING AUGUST 24, 1888.

Mason, Charles F., assistant surgeon U. S. A. Ordered to Fort Washakie, Wyo. Ty., for duty. Paragraph 5, S. O. 190, A. G. O., August 17, 1888.

Vollum, Edward P., lieutenant colonel and surgeon U. S. A. Leave of absence extended two months. Paragraph 17, S. O. 192, A. G. O., August 20, 1888.

Appel, Daniel M., captain and assistant surgeon. Ordered to Fort Bliss, for temporary duty. S. O. 77, Department of Texas, July 25, 1888.

Cowdrey, Stevens G., captain and assistant surgeon. Granted leave of absence for one month. S. O. 77, Department of Texas, July 25, 1888.

Woodhull, A. A., major and surgeon U. S. A. Relieved from duty with Army Retiring Board, Fort Leavenworth, Kan. Paragraph 10, S. O. 190, A. G. O., August 17, 1888.

Ainsworth, Fred C., captain and assistant surgeon U. S. A. To proceed to Atlanta, Ga., and inspect the new Army Hospital at that place. Paragraph 18, S. O. 192, A. G. O., August 20, 1888.

The meteorological record for the week ending August 18, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, Aug. 18, 1888.	Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.		Velocity of Wind.		State of Weather.[1]		Rainfall.

Mean, the Week.															

[1] O., cloudy; C., clear; F., fair; G., fog; H., hazy; S., smoky; R., rain; T., threatening; N., Snow; *T., trace of rainfall.

OWEN, W. O., JR., captain and assistant surgeon U. S. A., Fort Leavenworth, to report for temporary duty to the commanding officer, Fort Gibson, I. T. Paragraph 1, S. O. 104, Department of the Missouri, August 20, 1888.

HEGER, ANTHONY, surgeon U. S. A. In addition to his other duties to attend to the duties of the medical director, Division of the Atlantic during absence of Col. Charles Sutherland. Paragraph 4, S. O. 170, Division of the Atlantic, August 18, 1888.

WOOD, LEONARD, assistant surgeon U. S. A. To proceed from Fort McDowell to San Carlos, A. T., and carry out the instructions of the Department Commander. Upon completion of that duty to return to proper station. S. O. 89, Department of Arizona, August 1, 1888.

JANEWAY, JNO. H., major and surgeon U. S. A. Granted leave of absence for one month on surgeon's certificate of disability. Paragraph 2, S. O. 41, Division of the Pacific, August 8, 1888.

MANS, LOUIS M., captain and assistant surgeon U. S. A. Having completed rifle practice at Camp S B. Luce, Fisher's Island, N. Y., to return to his proper station (Fort Schuyler, N. Y. H.) Paragraph 1, S. O. 171, Division of the Atlantic, August 20, 1888.

WRIGHT, JOSEPH P., major and surgeon U. S. A. Detailed as member of Army Retiring Board, Fort Leavenworth, Kan., vice A. A. Woodhull, major and surgeon U. S. A., relieved. Paragraph 10, S. O. 190, A. G. O., August 17, 1888.

SUTHERLAND, CHARLES, colonel and medical director. Directed to inspect the Medical Department at Forts Brady, Mackinac and Wayne, Mich., Forts Porter, Niagara, and Ontario, New York, Madison Barracks and Plattsburg Barracks, New York, Fort Preble, Me., Fort Warren, Mass., Fort Adams, R. I., Fort Trumbull, Conn. Paragraph 7, S. O. 168, Division of the Atlantic, August 16, 1888.

GORGAS, WM. C., captain and assistant surgeon U. S. A. Leave of absence granted in S. O. 177, A. G. O., August 1, 1888, revoked and ordered to proceed to Camp Monte Sano, Huntsville, Ala., and report in person to the commanding officer thereof for duty, relieving Major Harvey E. Brown, surgeon. Paragraph 8, S. O. 187, A. G. O., August 14, 1888.

TORNEY, GEORGE H., captain and assistant surgeon U. S. A. To proceed to St. Augustine, Fla., *via* Palatka, accompanying the U. S. Troops thereat to Huntsville, Ala., as medical officer, and thereafter to return to his proper station (Fort Monroe, Va.) Paragraph 4, S. O. 165, Division of the Atlantic, August 13, 1888.

SMITH, JOS. R., surgeon and medical director, Department of Dakota. To inspect Forts Pembina, Totton, Buford, Abraham Lincoln and Yates, D. T. Paragraph 4, S. O. 77, Department of Dakota, August 13, 1888.

OBITUARY. HENRY F. QUACKENBOS, M.D.

Dr. Henry F. Quackenbos, a well-known New York practitioner, died at his residence August 21st, after a lingering illness. He had for a considerable time been suffering from chronic Bright's disease, but the immediate cause of death was pneumonia. He was born September 20, 1819, in New York, of which city his father, Dr. Nicholas I. Quackenbos, was also a native. Both father and son were graduates of Columbia College. In 1840 Dr. H. F Quackenbos was graduated from the College of Physicians and Surgeons, New York, and he afterwards went abroad and pursued his medical studies in London Edinburgh and Paris. While residing at the latter capital he was appointed surgeon of a brigade commanded by General Pellisser, afterward Duke of Malakof, and with it he served in the French Campaign in Northern Africa against the Algerians. He then returned to New York, and during the cholera epidemic in 1849, he was in charge of Bellevue Hospital, where his devoted and energetic services won him marked distinction. Dr. Quackenbos had a very extensive private practice, particularly among members of the theatrical profession, and from the date of its organization he was honorary physician of the New York Dramatic Fund Association. The last prescription he ever wrote was for Mr. Davidge, the genial comedian who recently died while on his way across the continent to California. For many years he attended the late Edwin Forrest, who, it is said, if taken ill while travelling, would always send for him, however distant from New York he might be. Dr. Quackenbos leaves a widow and one son.

HENRY O. STONE, M.D.

Dr. Henry Osgood Stone, who died August 23d, at the age of sixty-seven, at Salem, in the very house where he was born, was one of a large family of brothers, two of whom, the lamented Dr. John O. Stone, of New York, and the subject of this notice, became distinguished in the medical profession. Dr. Stone graduated at Harvard in 1841, and as M.D., at the University of Pennsylvania in 1844. After two years spent in Europe, he established himself in Boston, where his accurate knowledge, excellent judgment and self-sacrificing devotion soon made him conspicuous; although these qualities were united with a modesty which shrank from praise. Amply qualified in all departments of the profession, he had a special aptitude for surgery. But his health was never robust; and, after the death of his father, at the desire of his family, he returned to his native city, and became a welcome addition to the list of Essex County practitioners. Frequent intense attacks of migraine, to which he was subject, and which were especially induced by railway travel, compelled him to decline consultations out-of-town, and finally led him to withdraw from active practice; though he always retained a keen interest in whatever pertained to his profession; and he found congenial resources in books and in the exercise of a large benevolence. Highly cultured, refined in word and deed, cheerful, dignified and independent, but of great sprightfulness and wit in conversation, he filled a place not to be supplied in his family, in the large circle of his friends, and in the community in which he lived. Many of us can say, "I would that Heaven had made me such a man."

Dr. Stone's decease was sudden: A strange sensation in the head on Wednesday was followed by a partial paralysis on Thursday; but he continued conscious, able to talk, and fully aware of his condition; and at three in the afternoon of that day he quietly passed away.

THOMAS T. SABINE, M.D.

Dr. Thomas T. Sabine, the distinguished surgeon, son of Dr. Gustavus A. Sabine, who survives him, died August 23d, having been ill for some time with a complication of diseases. He was graduated from the College of Physicians and Surgeons, New York, in 1864, and in 1879 was appointed Professor of Anatomy in the College. For a number of years he was attending surgeon to Bellevue Hospital, St. Luke's Hospital, the New York Orthopædic Dispensary and Hospital, and other institutions, and he was highly esteemed for his many genial qualities no less than for his marked professional ability and rare skill as an operator.

Original Articles.

THE BACTERIA OF THE ALIMENTARY CANAL ESPECIALLY IN THE DIARRHŒAS OF INFANCY.

BY JOHN A. JEFFRIES, M.D.

THAT the interest lately developed in the study of the relation of bacteria to the diarrhœal diseases of infancy is justified will probably be acknowledged by all. On the other hand, owing to the recent development of bacteriology and the obscure way in which some of the most important articles have been published, those not actively studying the subject have but slight ideas of the advance made, advance already giving results in practice.

Both treatment and prophylaxis have improved. An infant can now cross the ocean provided with a supply of milk, cream mixture, or the like, sure to keep fresh, and identical with the food of the nursery. We are now justified in looking forward to another stride in the difficult subjects of artificial feeding of infants and the intestinal troubles of the same. The last great step was made by the chemical study of foods and the general realization of the fact that cows' milk is not mothers' milk, and a growing belief that were young animals fitted to feed on vegetable food nature would not have taxed the parents so heavily to provide an animal food. All the higher forms of life conform to this law, the helpless young are fed on animal food. We see this not only in the milk of mammals, but in the insect food of the helpless young of birds.

Bacteriology has now shown that, provided we start with a food chemically right, care must be taken or our worst foes, bacteria, will quickly invade the field, and, as if by the wave of a wicked fairy's wand, change the whole into poisons. Not only do bacteria work harm from without and within the body, but certain forms appear positively beneficial, inasmuch as by preemption of the alimentary canal they exclude more noxious forms.

The cavity of the mouth and throat offer little of importance to the subject. Many forms of bacteria are known to occur and to play a causative part in certain local diseases, as decaying teeth, thrush, and the like. Again, forms pathogenic to animals commonly occur, and forms known to be so to man are by no means rare. Yet on the whole the flora of the mouth is fairly constant, as shown by Vignal,[1] and Miller,[2] and chiefly of interest not for the harm it does, but for the converse. How is it that so many noxious forms existing in the mouth and being swallowed with the food and saliva disease is not vastly more rife? This is an interesting question. Unfortunately, as yet replies can only be made in general terms, that the epithelium of the mouth, true skin, is thick and the parts beneath very vascular, thus offering decided mechanical difficulties to the entrance of bacteria, and a prompt, powerful response from the system to any threatened invasion.

Once arrived in the stomach it has, until recently, been generally held that the bacteria would be killed by the hydrochloric acid, perhaps digested by the pepsin. Like other mistaken beliefs it is difficult to trace this to its source, or to collect and arrange the arguments in its favor.

Bienstock [3] seems to have been the first to put this idea forward, supported by experiments. This author held that only four or five kinds of bacteria occurred in the intestines, and on experimenting with those in a spore-free condition found them to be killed by a 2 % hydrochloric acid solution.

Koch first showed that the vegetative form of the anthrax bacillus was unable to resist the action of the hydrochloric acid during the normal course of digestion of vegetable eaters, but that the spores could pass through.

Koch, however, also pointed out in relation to the cholera bacillus that the empty stomach is not acid, that all the food does not stay there for hours, and that time is required to bring the hydrochloric acid up to the normal, 2 %.

We now know, thanks to the studies of Miller, De Barry and Escherich, that living bacteria are to be found in the stomachs of man and the animals, while the literature on sarcina ventriculi, a special form, beginning with the note by Goodsir [4] in 1842, has grown to large proportions in the work of Falkenheim [5] and others.

Miller [2] has isolated several forms from the digestive tract, and studied the effect of artificial digestion on pure cultures, but disregarded the question of spores. This was unfortunate, as it has always been granted that spores could pass through the stomach, yet it is improbable that spores existed in all his cultures, such not usually being formed under the conditions with which they were grown. He showed that the full period of digestion with a .16% hydrochloric acid solution was required to affect the forms studied. Also, Miller found that, contrary to the statements of Bienstock, eight forms found in the mouth occur in the stomach, and twelve in the stools. His final conclusions are that all the forms studied could pass through the stomach during the first part of digestion. Here it is of importance to remember that the food begins to pass through the pylorus in from fifteen to twenty minutes after eating.

In a later article Miller returned to the subject and showed that four kinds of gas-producing forms isolated by himself from the stomach of a man, were able to pass through the stomach of a dog. Miller mixed pure cultures with the food and fed four dogs, later killing them two and a-half, six, eight and nine hours after feeding. In the first two the stomach and intestines were found acid, in the third the lower part was alkaline, and in the fourth the entire digestive tract. All four kinds were again isolated from the stomachs, small intestines and rectums of the first three dogs. No living bacteria were found in the stomach of the fourth dog. The dogs suffered from diarrhœa. Lastly Miller took a milk culture of his first species and suffered sufficiently to forego all further experiments on himself.

This last set of experiments shows clearly that bacteria can pass through the stomach into the intestines and live for a considerable time, but is open to the same objection as his first set, the failure to exclude spores.

De Barry[6] studied the vomitus ejected by a man, and found seven species besides the mycelium of a mould. His work, however, was not done in strict accord with modern methods.

The most recent and conclusive work has been done by Macfadyen,[7] to whose very able article all students of the subject are much indebted. He experimented with pure cultures of harmless and pathogenic forms exposed to the action of pepsin, hydrochloric acid, and the two together in various strengths. As results he found that pepsin had no effect, while it required the action of a .05% to a .3% solution of hydrochloric acid for four hours at 37° centigrade to kill the various species used. The comma, Finkler-Prior and bacillus prodigiosus were killed by the .05% solution, while .3%, fifty per cent. more than the normal human standard, was required to kill the ordinary micrococcus of pus or the bacillus of typhoid fever. The absence of spores was insured in every case.

Next Macfadyen followed up his test experiments with some on the dog. Dogs fasting for twenty-four hours were fed with foods containing pure cultures of the pus micrococcus, and killed after five hours. All showed large numbers of the aureus throughout the digestive tract, and especially numerous in the lower parts. Dogs not fasting gave the same results.

Lastly, Macfadyen tried to pass the more perishable forms through the stomach, and found that by giving a thirsty dog water, containing the culture, to drink, any form could be introduced into the intestines, even the cholera bacillus. Under such conditions, common ones among men during hot weather, and notoriously unhealthy, the water scarcely stops in the stomach, but passes through the pylorus almost as soon as swallowed.

It is thus clear that the stomach offers but an insecure protection, many forms outlasting the test of full digestion in the dog, and any form being able, under natural conditions, to pass the stomach. The dog's stomach is a fair test, since the acid is the active principle, and more abundant than in man.

That the bacillus of tuberculosis can pass the stomach, as shown by feeding experiments, is well known to all.

Of the morphology and biology of the forms found in the stomach little is known. The field is a new one, and the species have not been sufficiently described to enable others to recognize them with certainty. Miller has found five kinds which give off carbonic dioxide and hydrogen gas, lactic, acetic and butyric acids being formed. In some cases an inflammable gas is known to have been formed in the stomach, probably marsh gas.

Of the flora of the intestines much more is known than of that of the stomach, thanks to the work of Bienstock, Miller, Brieger, Vignal and Escherich, not to mention the facts brought out in the study of typhoid fever and cholera.

Bienstock[8] was the first to attack the subject by means of cultures. Unfortunately his methods were inexact, and he shut his eyes to facts long revealed by the microscope. This led him to claim the existence of only four or five kinds of bacilli in the fæces, hence in the intestines, and to deny the existence of micrococci. To one of the forms he attached special fermentative and digestive powers, which he held were of decided assistance to the process of digestion; thus from experimental grounds advancing Pasteur's idea that, were it not for the action of the bacteria in the intestines our digestion would fail, and human life become impossible, — a very pretty theory which has by its sensational nature recommended itself to many, but has failed to find support in facts, as yet discovered. In his last article Bienstock entirely dropped this subject, and it is only mentioned here as it has found its way into not a few books.

The last form described by Bienstock is his drumstick, a very powerful decomposer of albumens, and not to be found in the fæces of sucklings. In regard to this form Bienstock again seems to be in error. No one else has found it, but it has been shown to be a very dangerous source of contamination of the various nutritive media employed, being very hard to kill. Escherich at one time described the form as occurring, but later found it to be a contamination.

The researches of Brieger,[9] Vignal,[10] Stahl[11] and Escherich,[12] have now proven that a large number of species may occur in the fæces. Brieger isolated two new kinds, one a micrococcus, which turns grape or cane sugar into ethylalcohol, with a trace of acetic acid; the other, the well known Brieger's bacillus. This species occurs in vast numbers in the fæces, ferments sugars and decomposes albumens.

Vignal isolated ten species from the fæces, six of these being also found in the mouth. Of these some produced acid fermentations and gas. Unfortunately they were not studied sufficiently to show their effects on digestion.

Miller has already been referred to in treating of the stomach; the inaugural dissertation of Kuisl,[13] has not been seen.

This brings us to the work done by Escherich, and the conclusions to be drawn from the same. This author studied the fæces of infants, the intestinal contents at autopsies, and found a large number of kinds. Among them, a small bacillus capable of converting milk sugar into lactic acid, carbonic dioxide and hydrogen gas being evolved, either in the presence or absence of air — in scientific parlance, a falcultative anaërobic species, his bacillus lactis aërogenes. Escherich also studied and described at length the action of Brieger's bacillus under the name of bacillus coli commune.

Both of these forms are fatal to guinea-pigs and rabbits when introduced into the venous system. Post-mortem examination, showing the spleen and kidneys normal, marked injection of the upper part of the intestine, mucous membrane swollen, chyme thin, alkaline, mixed with much mucus, Peyer's patches appearing as swollen, resistant, bluish-red spots through the serous coat; in places, superficial epithelial loss. With Brieger's bacillus, diarrhœa also occurred at times.

In addition to the two pathogenic forms just mentioned, Escherich found proteus vulgaris in meconium streptococcus coli gracilis, bacillus subtilis, and several other forms of less interest.

The great point is that by the examination of a large series of cases Escherich has been able to establish the fact that the kinds occurring in the fæces vary with the food; that is, the intestinal contents.

Starting at birth with the sterile meconium, consisting of mucous, epithelium and the like, infection by the mouth and rectum quickly occurs, and in a short time most any form may be found, but chiefly putrefying forms, as proteus vulgaris. With the suckling of the child and the substitution of the refuse of the milk and secretion of the digestive tract for the meconium, a sharp transition occurs. Instead of the generally distributed forms causing decomposition, only two kinds are regularly found: B. lactis aërogenes and Brieger's bacillus; the first chiefly in the upper parts of the intestine, the second in the lower parts. Passing on to the period of mixed diet, quite a number of forms appear, among them the streptococcus coli gracilis, the putrefying green fluorescing, a tetrad coccus, and several kinds of yeasts. This brings us to the pith of the subject: why are the flora so limited in the milk-eating infants and so diverse in others? What drives the forms found in the meconium out? That they can live there is clear, as shown by their presence the day before. Again, what prevents forms so common with meat diet from gaining a footing? It is not the milk alone, for milk is an almost universal food for bacteria, and all the kinds found in the intestines thrive in it.

Escherich answers as follows: the bacillus lactis aërogenes and the milk diet keep out the other forms.

Formerly, even before the nature of ferments and putrefactive processes were clearly understood, the significance of this question was seen. The chyme is a mass admirably adapted for putrefaction or fermentation, yet, ordinarily, but little of either occurs. It is an alkaline, or, as in the milk-fed, acid mixture rich in albumens, fats, and the starch group, amply provided with water and warmth. Such a mixture outside the body at an equal temperature would quickly decompose. It was generally held that some preservative action was exerted by the digestive juices; Bidder's and Schmidt's dogs with biliary fistulæ were held to explain the whole. These dogs, deprived of their bile, became emaciated, and suffered from diarrhœa and decomposition of the intestinal contents. Thus it seemed clear that in the absence of the bile decomposition occurred; that is, that the bile was a powerful germicide or germ-inhibitor. During the last few years, however, different results have been obtained in cases of biliary fistula. Röhmann's[14] dogs did not suffer from diarrhœa or putrefaction in the intestines; hence it is clear that the bile is not the cause of prevention. The diarrhœa, if present, is due to the large amount of fat passed on to the lower intestines.

Maly[15] and Emich[16] ascribed value to the bile acids, especially the taurocholic, basing their results on crude methods; and Lindenberger,[17] really leaving the subject, attributed the action to the organic acids in combination with the bile.

[14] Röhmann. Beobachtungen an Hunden mit Gallenfistel. Breslau, 1882.
[15] Maly. Hermann's Physiologie, v, p. 184.
[16] Emich Sitzberich. d. Akad. d. Wissenshft. Wein., 1882.
[17] Lindenberger. Upsula Forhandlingar, 1884.

All this argument and belief in the decided germicidal action of the bile occurred in the face of the well-known fact that bile itself will decompose.

From a bacteriological standpoint, Miller has shown that a ten per cent. solution of bile, if anything, favors growth. Macfadyen has studied bile, bile salts, and bile acids in varying strengths. The only positive results were got with the acids, these arresting development of bacteria if sufficiently strong, especially taurocholic acid. Neither acid had much effect, and least of all on the forms causing putrefaction. Proteus vulgaris was only arrested by a strength of from one to two per cent. The pathogenic forms were arrested by a much smaller quantity, from one to one-half per mille.

It is thus clear that other causes must be sought for. One of these is to be found in the lack of oxygen in the intestines, as pointed out by Escherich and strangely forgotten by others. There is certainly very little free oxygen in the chyme, if any; not only is it scarce in the food at the start, but is taken up by the chemical changes during digestion, and also by the intestines. This clearly must be a potent factor, for the majority of bacteria require a fair supply. Accordingly, many bacteria are found in the fæces which will not grow in the air, as shortly stated by Macfadyen, and the mass of those isolated in the air are able to grow without it.

This apparent contradiction, the absence of oxygen in the intestines, and the presence of both aërobic and anaërobic bacteria is probably explained by the ability of the aërobic kinds to drawn oxygen from oxyhæmaglobin. They thus breathe through the intestines, as it were, when in close contact with the walls, while the anaërobic kinds live in the mass of the chyme, and do not, so far as we know, reduce oxyhæmaglobin.

Escherich, though he points out the absence of oxygen, does not seem to give it full value, or rather forgets the subject in treating of the action of his lactic acid bacillus. As before stated, this form is regularly found in great numbers in the upper part of the intestines of milk-fed children. Here it converts a considerable part of the milk-sugar into lactic acid (Baginsky[18] says acetic acid, but has given no proof), and thus prevents the other forms from growing, most forms being very susceptible to an acid reaction, and especially to the organic acids. The action of salicylic acid is known to all, and recent experiments, of which Macfadyen's (the last are the best) show acetic, butyric, and lactic acid to be efficient germ-inhibitors in strengths of from one to one-half per mille, according to the species.

In milk-fed infants another point is the comparative inability of bacteria to attack casein, so that the bacteria are literally starved.

To sum up, we may conclude that the bile acids, lack of oxygen, lack of suitable albumens, and the presence of organic acids are the causes of immunity from the putrefying and fermenting kinds of bacteria to which we are exposed. Certain forms are probably limited by the lack of water, that is, fluid state, doing poorly if unable to swim freely about. It must not, however, be supposed that bacteria are scarce in the intestines, on the contrary they form a large part of the dry substance of the fæces.

Brieger's bacillus has been passed by us as of no im-

[18] Baginsky. Deutsch. Med. Wochenschr., 1888, Nos. 20 and 21.

portance in reference to the above. It thrives in the lower part of the intestine, feeding on the refuse passed on from above, and secretions and excretions of the tract. The species has a fermentative action, producing alcohol and a trace of acetic acid (Brieger), a powerful action on proteids and breaks up fats (Escherich).

Passing from the normal condition of the intestines to those of indigestion and diarrhœa, more especially of infancy, while there is little worked out to a conclusion there is much of value to be applied in treatment. It is known that in the cases of indigestion accompanied by the eruction of gas and not a few cases of vomiting bacteria are playing an important role, often are the causes. Such cases of indigestion are usually characterized by the eructation of gas after meals and a sense of oppression due to the disturbed digestion and dilatation of the stomach. A certain small amount of lactic acid occurs in our food, the same is true of acetic acid, but butyric acid should be practically absent. In normal digestion a small amount of the first two is of no harm, and one of them seems to play an important part in the upper part of the intestines. Butyric acid is an offensive compound and acts as an irritant in the stomach. Any of these acids produced in quantity in the stomach are injurious, tend to cause and keep up catarrh. The gas given off during the production of the acids not only oppresses by unduly dilating the stomach, but must interfere with the mechanical action of that organ. We now know that the stomach does not lie across the body but more up and down, the pylorus being below. In this position the food tends to fall to the pylorus and is constantly worked up towards the cardiac end by muscular action, the more fluid parts running back and down into the duodenum. Gases, easily compressible as they are, must interfere with this pumping or driving motion and render the mechanical work of the stomach less effective impeding an intimate mixture of the food and gastric juices and thus hindering proper digestion.

As pointed out by Taube,[19] since the stomach dilates chiefly on the side of the greater curvature, hyper-extension brings the curvature below the pylorus. In this case all fluids will gravitate to the pocket thus formed instead of to and through the pylorus.

Recently Klemperer,[20] in studying the hydrochloric acid in the stomach has developed the fact that much of the disagreement as to the hydrochloric reaction in cases of cancer of the stomach, and dilatation depends upon the bacteria contained in the juices. The bacteria act in two distinct ways. First, according to the well known law that a mixture of acids combine with a base in quantities according with the strength of the acids, the various organic acids produced by fermentation drive out a small part of the hydrochloric acid. Second, other products of the bacterial growth as the ptomaines, form compounds with the hydrochloric acid sufficiently strong to prevent the bluing of methyl violet, but not sufficiently strong to resist the other tests commonly used. The acid thus combined is taken away from the digestive process, which is proportionately weakened. In normal digestion the amount of hydrochloric acid thus taken up varies from .6 to 1 %, while in a case of cancer it rose to 2.5 %.

Klemperer worked not only with the ptomaines produced by the growth of Brieger's bacillus in milk, but also with those isolated from the gastric juice in a case of cancer of the pylorus.

The diarrhœal troubles of adults have not been sufficiently studied bacteriologically, and little is known of them. In a few cases examined by myself the proportion of Brieger's bacillus to the other aërobic forms has been reduced, and two or three putrefying forms decidedly increased, among these the putrefying green fluorescing. Pure cultures of this plant give off an offensive odor closely resembling those of the stools from which they were taken.

In this connection it is interesting to note that the period of raw small fruit. salads and the like, is the period of intestinal troubles. In other words, the consumption of raw — that is, not sterilized — foods, which by their nature and surroundings are exposed to all sorts of bacteria, goes hand in hand with the prevalence of functional intestinal trouble. The small fruits are eaten whole, together with a hoard of bacteria, large fruits eaten later are peeled, that is, prepared, much like a potato for a pure culture.

On the whole, bacterial overgrowth in the stomach tends to the so-called ferments in the intestines to putrefaction.

Of the summer diarrhœas of infancy we really as yet know nothing specifically. Bacteria are very abundant, the putrefying group coming forward. Lately Escherich, in an article of which I have only been able to procure a notice, reports that the spiral forms are unusually abundant in cases of diarrhœa, but regards them as a result rather than cause of the trouble.

The only claim worthy of consideration to the discovery of a specific organism has been put forward by Lesage.[21] This author describes a form as constantly occurring in great numbers in the stools of a certain class of diarrhœas, the clinical aspect of which corresponds with an ordinary case with an elevated temperature. This plant produces a green coloring matter, is easily grown, and, according to the author, has a very bizarre method of development. Not only does the plant show a tendency to grow into threads, later splitting up into bacilli, but it produces endogenous spores, which in turn give off a number of daughter spores by budding, these growing into bacilli and threads. So far as known to me this is an utterly new method of growth among bacteria, indeed, removes the plant entirely from the class. Another peculiarity is that the spores are more rapidly and deeper stained than the vegetative cells. This plant, Lesage states, produces green diarrhœa if introduced into the intestines or stomach, and one syringe full introduced into the ear vein of a rabbit produced a slight green diarrhœa. The plant was recovered in the intestines. Pure cultures were found to be quite sensitive to lactic acid, so Lesage adopted a lactic acid treatment for these cases, giving large doses, and reports extremely favorable results, in fact, a specific action.

As yet no confirmation of Lesage's observations have come to hand. My own search for the plant in the few suitable cases to be found so early in the year have failed. The nearest thing to it found was the putrefying green fluorescing bacillus. This has a green color, but lacks all the other characteristics of Lesage's plant. Baginsky has discredited Lesage's results, and considers the plant to be the green fluorescing bacillus, which it certainly is not, for the plant

[21] Archiv de Physiol., 1888. Feb. 15th, p. 212.

has no such mode of growth. The entire thing is very strange, and needs abundant confirmation before being accepted. At the present time there seems to be no reason to expect a specific, but rather that the whole trouble begins as a reaction to noxious products of various species and runs on in the course of time from a condition of pathological physiology to one of pathological anatomy, loss of substance occurring in the epithelium.

With the growth of our knowledge of the active part played by bacteria in the various troubles of the alimentary canal a decided change has occurred in the treatment of the same. These changes have for the most part been instituted without any clear idea of their action, survived in virtue of their efficacy, to be later modified, perfected and guided by the light thrown upon them by bacteriology.

The recent changes in the treatment of gastric catarrh so ably presented in this journal by Knapp, at once reveal the fact that an efficient anti-germ treatment is now followed; not only is the stomach washed out, that is, the field weeded, but the soil mucous and refuse of food is removed, and a weak poison left in its place at times. The well-known use of creosote, sublimate and calomel probably owe their utility to their impairing the bacterial growth. Various efforts have been made to kill the unwelcome guests in the intestines by means of drugs. In the diarrhœas of infancy this subject has been attacked from three sides, by the use of drugs, by the care of the food, and by change of diet. All three methods are rational and worthy of use, often together. Other things being equal, modern physicians would eschew drugs, and the laity rush for them. They would rather take medicine than trouble. From a therapeutic side efforts have been made to find something to kill the plants and not the child. These drugs may be classed as mild antiseptics, as organic acids and antiseptics, soluble and insoluble. Barring Lesage, there does not seem to be any strong enthusiast in favor of the acids; though the curative effect of sugar has been pointed out by some. Sugar acts by being changed to acids in the intestine. With the germicides there is still quite a rage, due in large part to the assumed destruction of the germs. As a fact the germs are only slightly reduced in numbers by the most successful drugs. A drug to be antiseptic must be soluble, if soluble it is at once taken up by the intestines, thus being removed from where it is wanted and put where it is not wanted in the child's system. If insoluble, or rather slowly converted into a soluble active form, the action is weak, and absorption still occurs, only in small quantities throughout the gut instead of all at once in the upper part. Reasoning gives hope of but slight success with germicides, while the great number of things recommended strongly suggests insufficiency of all. Were any drug markedly successful the others by selection would quickly be excluded.

Again, if, as appears, Escherich's ideas of the value of his lactic acid bacillus are correct, we would by the use of germicides only open the field to any form that might chance to gain access.

Possibly there is hope of better results to be obtained by the use of drugs directed, not to the destruction of the germs, but to the alteration of their poisonous products. No effort seems to have been made to attain this result, except by the administration of acids and alkalies. I have suggested that iodoform [27] may have this effect. It certainly removes odor from putrid fluids quickly, though it does not kill the bacteria. This may be a simple case of concealment, but as the effect is a half-hour in development it is doubtful. We know that the administration of iodoform removes the aromatic compounds from the urine. Unfortunately, iodoform is decidedly poisonous, causing fatty degeneration, and its products secreted in the saliva combine with the metals of our eating utensils to form most revolting compounds in the mouth.

Naturally it has long been the custom when the infant suffered on one kind of food to change to another. Thus peptone solutions, albumens, and various starch and dextrine solutions are still much used; to say nothing of the various patent foods consisting when given, of cow's milk, starch and its derivatives. Wine whey, a very old preparation, seems to have dropped out of use in this vicinity, but still holds its own in England and Ireland.

All these efforts to find a more satisfactory food have been the natural result of failure, and directed purely on empirical grounds; often change after change being made until a successful food was hit upon or the child died. Escherich's work now opens the field to more intelligent work. The secret of the value of change of food according to him lies in the effect upon the bacteria. Some of these attack the starches, others sugars, or both sugars and starches, while at the opposite end of the series albuminates are attacked and putrefaction results.

Either group, ferments or putrifiers, is undesirable. The ferments act by the production of various acids, chiefly from the milk sugar. In small amounts, as in the case of bacillus lactis aërogenes, the acid seems to be of benefit, certainly does no harm as it regularly occurs in healthy breast-fed infants. In larger amounts, however, it must tend to over-acidify the contents of the intestines and upset the action of the digestive fluids.

Bokai [28] has recently shown that the various organic acids have a very decided effect on the motion and blood-supply of the intestines. The intestines of rabbits were exposed in a warm normal salt solution bath. All the acids were found to increase peristalsis, lactic, succinic and acetic acid with constriction of the bloodvessels; valerianic, butyric, formic, propri-onic, capric and caprylic acids with dilatation of the same. One or two grammes exhibited by the mouth produced diarrhœa, smaller doses a catarrhal state, and larger a positive inflammatory state.

These observations pave the way to Baginsky's theory, practically an acceptance of Escherich's ideas, that the lactic acid bacillus growing in superabundance irritates the digestive tract, causing diarrhœa, and if continued, brings about its own death by the superabundance of acid produced. In this case the acid is quickly passed on and the gut is left open to the putrefying alkali frequenting forms.

The value of Escherich's work here comes in; he suggests that the change of food should be governed so as to starve out the rampant ferment. If the ferment is an acid one, to give a food free from sugars and starches, if an alkaline one, free from albumens and

[27] Jeffries. Am. Jour. Med. Sciences, 1888, January. Behring has just shown this to be true of cadaverin. Deutch. Méd. Woch., Aug. 9, 1888.

[28] Bokai. Archiv. f. Experim. Path. u. Pharm., 1887. Vol. xxiv, p. 153.

calculated to encourage the lactic acid bacillus to a normal growth. In the first case Escherich suggests peptone solutions, in the second, dextrine solutions.

Baginsky accepts Escherich's principles, but claims that he has forgotten the child and that empirics have their place. He points out that peptones are known to be poisonous if introduced into the system, and often cause diarrhœa. Unfortunately, Baginsky is not clear as to what should be given. Dextrine is also objected to on account of the impurities contained and milk sugar suggested as a substitute.

Lastly, Escherich has refuted Baginsky's objections and referred to the favorable results obtained by Ehring. That cane sugar, glycerine, dextrine and starch stop putrefactive processes in the intestines is proved by Hirschler's experiments. This author showed that the products of decomposition were absent in urine and fæces of animals treated with these foods.

Baginsky attaches great value to calomel in the early stages, on purely empirical grounds, since Morax has shown that the drug does not affect the aromatic group.

It is probable that kephir will prove to be a valuable food in the cases of acid diarrhœa. This is milk fermented by the kephir grains composed of two or more kinds of bacteria. By the growth of the plants the milk sugar is broken up; alcohol, lactic acid, carbonic dioxide and hydrogen being formed. The injurious constituent of the milk, the sugar, is removed, and the casein is curded in fine flakes and so cannot form a mass in the stomach.

Is the reaction of the stool a sufficient index to the ferment in the intestine? Escherich thinks it is, Baginsky and Vaughn[24] doubt it. Here the study of the urine by Morax,[25] Baumann,[26] and Hirschler[27] come into play. These authors have shown that the sulphuric ethers and aromatic compounds of the urines vary with the amount of putrefaction in the intestines. Thus by a quantitative analysis an exact knowledge of the ferment is to be obtained.

Though not treating of bacteria in the intestines, Vaughn's work on tyrotoxicon cannot be passed by, and leads the way to the last and most radical part of the subject, prophylaxis. Vaughn has isolated from milk, ice-cream, and the like an active poisonous compound, which produces symptoms much like those of cholera infantum. This compound, diazobenzol, is produced in milk excluded from the air, and at a temperature of at least 60°. The bacterium producing the trouble has not yet been found. It is very likely an anaërobic species.

Vaughn's article suggests that the tyrotoxicon plant may be the cause of cholera infantum, but does not frame the idea.

Very recently, Behring[28] has announced that cadavarin, pentamethylindiamin, produces death in guinea-pigs, with symptoms and post-mortem resembling Koch's artificial cholera in the same. Cadavarin is freely formed by the cholera bacillus in alkaline solutions, commonly occurs in decaying bodies, as indicated by its name, and may be, therefore, an element in the diarrhœas of infants and adults.

Taking up the subject of prophylaxis, it is clear that the general laws of health must be attended to, that mother's milk is better than cow's milk, and, as shown by Rotch,[29] that quantity and quality of all foods must be attended to. Over and above this, the feeling that the summer diarrhœas are due to changes in the food, that is, to bacteria in the same, has been steadily gaining ground for some time.

With this consideration in view, great care has been given to the food-supply, ice employed, and the like; also cooked food given.

In 1886, Soxhlet[30] published an article recommending the sterilization of milk by immersion in boiling water for forty-five minutes, the flasks containing the milk to be closed after being heated. Soxhlet made no bacteriological study of the subject, and simply took the curdling of the milk as a sign of infection. Measured by this standard, the milk kept about three weeks. Unfortunately, milk becomes full of bacteria and seriously altered before curdling occurs, and certain species do not curdle milk. Soxhlet kept the deadly, long sucking-tube, and advocated a very complex apparatus of bottles, cages, and water-baths.

In the summer of 1884, my attention was first directed to steaming the milk for infants, being guided by the custom of housewives. Receipts are to be found in the cook-books for preserving milk and cream for a long time, the principles of which are the addition of a moderate amount of sugar, then bottle, and all to be heated in boiling water for some time, the cork, also scalded, to be driven home while the whole was hot. In short, the whole of Soxhlet's method packed in a nutshell.

In 1887, on returning from Europe, my attention was again called to the subject, and every child under my care put, as far as possible, on steamed milk. Being pleased with the results, and learning that Dr. Ernst had used a similar method for three yeara, I determined to work the subject out from a bacteriological point of view, and obtain some reliable, simple method capable of general cheap application. The results were published in a paper,[31] from which I quote:[32]

"Stopper the flasks (that is, those from which the child is to be fed) with cotton-wool, and heat them in the oven for thirty minutes at a mild baking heat, or until the cotton becomes brown. Pour the requisite quantity of food into the flask, and then place in the heated steamer for fifteen minutes."

If this method is followed, the milk will keep for a long time practically free from bacteria and their injurious products. The first rule is a refinement, and, in view of the work of Wolfhügel and Beidel,[33] desirable. These authors have shown that pathogenic germs in washing water could cling to the vessels and infect milk put in them.

The steaming must be thorough, but any simple steamer will do, provided it is filled with live steam. The milk should be steamed *at once* on receipt from the milk-man; otherwise the child will get a sterile food already charged with the poisons of decomposition.

No expensive and complex apparatus is needed, and on a pinch an ordinary medicine-bottle placed in the

[32] Soxhlet's article was not referred to in my paper, as I did not then know of it, nor, indeed, have I been able to find any person present at the time it was read who had seen Soxhlet's article.
[33] Wolfhügel u. Riedel. Arbeit a. d. kaiserl. Gesundheitsamt., I, 1886.

tea-kettle will nearly fill the requisites. Cotton-wool is the proper stopper; it cannot be blown out, hence can be put in before steaming, and is germ-tight. Any stopper put in after steaming is not itself disinfected. When the child is to be fed, take out the cotton plug and put on a short rubber nipple. It is absurd to struggle with a sterile mouth-piece so long as the infant's mouth is swarming with bacteria: the value of the method lies in the integrity of the milk.

We thus see that a good start has been made, much knowledge gained, and much to be looked for. The very gaps in our knowledge show that the subject is a far-reaching one. Bacteria form a part, perhaps large part, in the balance of forces in the intestines, which results in normal digestion. Any disturbance, be it from the food, bacteria, or the intestines, throws the balance out and results in disease.

OBSERVATIONS ON THE SURGICAL TREATMENT OF MALIGNANT GROWTHS.[1]

BY MAURICE H. RICHARDSON, M.D., OF BOSTON.

Tumors of the Testicle. — Next in death-rate come tumors of the testicle. Seven out of nine are now dead. Of the living, one was probably tuberculosis, and the other a large-celled sarcoma. One died from the operation, one in two months, one in four, one in five, one each in nine, eleven and fifteen months. This is a very unfavorable showing, yet excision seems to be the duty of the surgeon, with the usual care in the consideration of the contraindications. The cord should be ligated as high up as possible, and any glands in the groin removed. The presence of glands affected beyond Poupart's ligament of course contraindicates the attempt.

Epitheliomata of Face and Scalp. — Cases heard from, 67; not heard from, 47; total, 114. Living, 34; without recurrence, 22; with recurrence, 12.

1878. Cases, 8. Living, 1. Dead, 7 — 1 at 24 m., 1 at 84 m., 1 at 84 m., 1 at 10 m., 1 at 96 m., 1 at 72 m., 1 at 12 m.
1879. Cases, 5. Living, 3. Dead, 2 — 1 at 48 m., 1 at 84 m. (no recurrence).
1880. Cases, 14. Living, 4. Dead, 10 — 1 at 72 m. (suicide), 1 at 16 m., 1 at 12 m., 1 at 36 m., 1 at 41 m., 1 at 84 m. (suffocated by gas), 1 at 7 m., 1 at 7 m., 1 at 30 m., 1 at 48 m.
1881. Cases, 4. Living, 2. Dead, 2 — 1 at 13 m., 1 at 60 m.

1885. Cases, 6. Living, 5. Dead, 1. 1 in hospital.
1886. Cases, 7. Living, 6. Dead, 1 — 1 at 22 m.

Cases, 67. Living, 34. Dead, 33. Av. 37 m.

I consider that this is one of the most important classes of cases. The number of operations on these as on many of the other classes has been much greater than the records show, because the milder cases have been treated as out-patients. The high death-rate in my list is due to this fact in part. I have no doubt that the percentage of cures among the out-patients has been very high indeed, because this form of cancer is one of the least malignant at the outset, and most easily cured by proper treatment.

Of one hundred and fourteen cases I have heard from sixty-seven, of which thirty-four are living and thirty-three dead. One has lived ten years; three, nine years; four, eight years; two, seven years; four six years; seven, five years; two, four years; five, three years; six, two years.

Of the thirty-three dead, there was no recurrence in four; two of whom died of old age, one was suffocated by gas, and one suicided. The average duration of life was thirty-seven months. One lived ninety-six months, four lived eighty-four, three seventy-two, one sixty months, etc., etc. One died from operation.

The replies which I have received in these cases have shown, in a most graphic way, the terrible ending of life in this form of malignant disease. No other class of cases emphasizes more strongly the importance of early excision, even to mutilation, in the early stages. Certainly no other form of cancer offers greater hope of cure than this, unless it be epithelioma of the lip when radically excised. I would advocate most strongly the earliest possible excision in all cases where the disease shows a tendency to penetrate to the deeper parts, or to invade such structures as the eye. In the superficial varieties where there is nothing but a scab on the skin, where the disease is hardly more than a keratosis, the curette or the cautery may be used, and in many of these cases such treatment has been followed by cure. But in the deeper kinds, where, for example, there is a deep ulceration of the inner canthus, I would advise and perform excision so deep and thorough as to ensure a healthy margin, *regardless of* any other parts whatever, even to enucleation of the eyeball. Here again we have to meet the natural objections of the patient, but our duty is not done till this has been impressed upon his mind. I have no doubt that some of the fatal cases in this list were useless operations. One at least was my own, which I should not for a moment think of undertaking now, where the cheek was extensively infiltrated, but no glands were involved as far as I could make out. Unless a wide margin is sure the disease should be let alone as far as any operation for cure is concerned.

In this connection I would like to say a word in regard to the use of the curette and the actual cautery. In the superficial cases nothing could be more satisfactory than the curette, or perhaps the cautery. Where the deeper layers of the skin have become involved or the subcutaneous tissues, I believe that these methods are worse than useless, — that is, as a means of cure. Both methods must fail of complete removal because it is impossible to see and recognize the healthy tissues when they are reached.

Cancer of the Lip. — Probably no class of cases offers a better outlook than this, if taken early, and if thoroughly treated. Of seventy-five cases, most of them severe, I have heard from fifty-one, with twenty-six living and twenty-five dead.

1878. Cases, 4. Living, 0. Dead, 4 — 1 at 12 m., 1 at 12 m., 1 at 12 m., 1 at 108 m.
1879. Cases, 6. Living, 2. Dead, 4 — 1 at 56 m., 1 at 12 m., 1 at 24 m., 1 at 11 m.
1880. Cases, 3. Living, 1. Dead, 2 — 1 at 29 m., 1 at —.
1881. Cases, 7. Living, 4. Dead, 3 — 1 in hospital, 1 in 60 m., 1 in 29 m.
1882. Cases, 5. Living, 2. Dead, 3 — 1 in 13 m., 1 in 10 m., 1 in 18 m.
1883. Cases, 6. Living, 3. Dead, 3 — 1 in 5 m., 1 in 23 m., 1 in 15 m.
1884. Cases, 5. Living, 3. Dead, 2 — 1 in 9 m., 1 in 29 m.
1885. Cases, 4. Living, 3. Dead, 1 — 1 in 25 m.
1886. Cases, 11. Living, 8. Dead, 3 — 1 in 24 m., 1 in 12 m., 1 in 15 m.

Cases, 51. Living, 26; dead, 25. Av. $26\frac{5}{51}$. Died without return, 4. Died of original disease, 21.

[1] Concluded from page 196.

1878 — no cases lived 10 years. 1879 — 2 lived 9 years. 1880 — 1 lived 8 years. 1881 — 4 lived 7 years. 1882 — 2 lived 6 years. 1883 — 3 lived 5 years. 1884 — 3 lived 4 years. 1885 — 3 lived 3 years. 1886 — 8 lived 2 years. Total, 28 cases living. With recurrence, 2; no return, 24.

As in the previous class, but one died from the operation.

The recurrence is very much more likely when the submaxillary lymphatics have been involved. I would not say that such infection is a contraindication, unless there is a large and adherent mass in the neck. The invasion of the jaw, also, makes the outlook very serious. Where, however, the cheek is infiltrated to any extent, and the lymphatics below the jaw are invaded, as well as the jaw, it seems to me that the case offers so little hope of permanent cure as hardly to justify an operation.

In early cases, it is important to bear in mind that the wider the margin, the better the chances of cure, and also that the lip is a very elastic thing. One thinks he is leaving a very wide margin when the lip is stretched, but examination of the shrunken part when it has been excised often shows a very narrow one. I would leave at least half an inch of healthy lip on each side of the V. It is a good rule in this operation, as in all others for malignant growths, where it is practicable, to excise the tumor with a wide margin in every direction, and then, and *then only*, consider the question of closing the hole.

Cancer of the Penis. — Cases, twenty. Replies, ten. Living, six; dead, four. Two are living at eight years, one each at seven, six, five, and three years. One dead in twenty months, and one each in seven, seven, and eight months. One of the dead had circumcision, one curette, and two were amputated. In one of the amputations the inguinal glands were dissected out. In one of the living, amputation followed circumcision. In another, circumcision was done seven years ago. In the remaining four, amputation was done at first.

I believe that all cases of cancer of the penis should be treated by amputation well down to the pubes, except in the most trivial and circumscribed ones. The adoption of so radical a rule in all cases as early as possible would, in the absence of glandular infection, bring the percentage of cures very high indeed.

As a method of cure, I think the curette or cautery a waste of time.

Malignant Disease of the Extremities. — Cases, eighty-nine. Answers, fifty-six. Living, thirty-seven; dead, nineteen.

1 lived 24 m.		1 recurrence at 3 m.	
1 " 36 m.		1 " 4 m.	
1 " 24 m.		1 " 2 m.	
1 " 84 m.		1 " 2½ m.

1 " 4 m.		1 " 20 m.	
1 " 12 m.		1 " 4 m.	
1 " 37 m.		1 " 1 m.	
1 " 6 m.		1 " 4 m.	
Average duration of life, 25⅔ m. in 9 fatal cases.		1 " 13 m.	
		1 " 36 m.	
Died from operation, $\frac{1}{9} = 11.2\%$		1 " 18 m.	
Total dead, 19. In hospital, 10.		Average recurrence, 11½ m.	
Died subsequently, 9. Died subsequently, without recurrence, 1. Died from original disease, $8 = 14.2\%$		Living, with recur'nce,	$1 = 1.7\%$
		" without "	$35 = 62.5\%$
		" with 3 "	$1 = 1.7\%$
		Total living . .	37

It is in this class of cases that we may achieve brilliant results by early and radical operation, and in no other may the failure be more dismal and complete by the use of half-way measures. The same rules of treatment apply here as to other parts, and the same contraindications. What I would urge is the more frequent resort to amputation in those cases which do not admit of satisfactory removal of the part itself. In infiltrating epitheliomata of the hand, sarcoma adherent to the bone, invasion of the lymph glands of the elbow or the popliteal space, without infection of the groin or the axilla, all forms of malignant disease of the bones — in all these amputation well above the diseased parts should be advised and performed, if the patient can be made to realize the necessities of the case. An analysis of these fifty-six cases will show most gratifying results of amputations, as compared with excisions of the tumors themselves. I have not had time to do this, but reserve it for a future paper.

Cancer of the Breast. — The number of tumors of the breast removed from November, 1877, to January, 1886, has been two hundred and seventy-four. I have received replies from one hundred and sixty-three. Of these, ninety-five are dead and sixty-eight living. Of the sixty-eight living, seventeen were not malignant. This leaves fifty-one living out of one hundred and sixty-three, 36 %. Of the living, I have found that eighteen were determined to be malignant by microscopic examination. In nineteen there was recurrence, twelve of which had not been examined by microscope, or, at least, the examination I have not as yet found. This would make the diagnosis of malignancy in the original tumor certain in thirty cases, recurrence being even more certain than microscopic examination.

There were twenty-three cases of death from the operation out of the whole number of two hundred and seventy-four, or 8.3 %. In the cases of cancer of the breast from the foundation of the Hospital to 1871, the mortality from the operation was twenty-three in two hundred and ninety cases, or 7.9 %. This, at first glance, is surprising, for the cases I have collected have all been done since the introduction of antiseptics. But the increased mortality is due to the greater thoroughness and severity of the operation.

The date of recurrence in sixty-two cases is 14.2 months. The longest immunity has been sixty-three months, and the shortest one month.

Cancer of the breast I have considered first in importance from the greater number of cases. From the tables it will be seen that the number of operations has not diminished during the past ten years. During 1887 and 1888, the number has been larger than ever before, and I venture to assert that the results will be more favorable. It does not seem to me justifiable to say, even in the face of these imperfect statistics taken from the Massachusetts General Hospital, many of them in Dr. Hodges's own service, that the operation is not successful enough to warrant renewed efforts, or that the operation is or is likely to be a thing of the past.

The percentage of deaths from operation is not large. Even with antiseptics, it seems to me that some must necessarily occur. The deaths from preventable causes have been surely diminishing. The operation, as it ought to be done, is a formidable one, but with a mortality of only eight per cent. it is not sufficiently great to weigh against the large percentage of permanent cures which is, I believe, sure to result from increased thoroughness of removal.

At my first operations on cancer of the breast in 1880, I determined to attempt to perform this operation in the most thorough and radical manner, espe-

cially as regards the axilla. I have since operated in about sixty cases. The results I do not know, except in a few cases done at the Massachusetts Hospital. In these the percentage of living has been large, and I think it is due to the method of dissecting the axilla. In all the cases where the disease has returned, it has appeared in the scar of the breast, and not in the axilla.

The method I have adopted, though there is, so far as I know, nothing new in it, is to make such a dissection of the axilla as I have made in the dissecting room. The incision is carried from the breast along the edge of the *pectoralis major* across the axilla and down the arm, directly over the axillary vein. All the tissues down to the *serratus magnus* are removed with a knife by a clean dissection, so as to take out all the lymphatic vessels. The axillary fat is then excised, and the axillary vein found and fully exposed as a landmark for future dissections, on the ground that the vessel is most easily avoided when its position is shown in full view. The aponeurosis which holds in the axillary fat and is attached to the coracoid process is next incised freely, which allows free dissection with the scalpel in and around the axillary structures. The fat can be separated from the vessels and nerves by clean incision till the whole is removed. I have never made this dissection in any case where I have not found some of the glands affected, even when nothing could be felt on the outside. The investigations of Dr. Whitney have also shown that this mass of fat contains, or may contain, clusters of cancer cells wholly independent of the glands, even when the glands themselves are not visibly affected. Other observers have found the lymphatics affected with malignant disease, even when not perceptibly enlarged.

These investigations alone show the necessity of dissecting out the axilla in all cases. There is no doubt that this method adds to the danger, as well as to the discomfort and impairment of the arm. Dr. Mixter has advocated a little different incision; namely, to carry the axillary cut well up on the *pectoralis major*, so as to close the axilla by untouched skin, which he fastens deeply to one of the serrations of the *serratus magnus* by means of a deep stitch. I have had little experience with this method, but it is claimed for it that there is little or no impairment of the movements of the arm afterward.

There is no doubt that this method, which ought to be followed in all malignant tumors of the breast, makes the operation a most formidable one. It is not an easy task to remove all the fat from the axilla without wounding any of the important structures it contains. Wounding the axillary vein is the greatest danger as regards immediate results, and is generally fatal in a short time. There is not so much danger of injury to either artery or nerve. There is, nevertheless, little excuse to be offered for cutting so large and prominent a vessel as the axillary vein, if the operator has ordinary skill and experience with the knife.

I do not agree with those writers who say that dissection of the axilla does not add to the dangers of the operation. It seems to me as absurd as to say that amputation of the thigh is no more dangerous than that of the leg. I have no doubt that it increases the mortality fully fifty per cent.

Another point in the operation of the greatest importance is the removal of plenty of skin over the tumor. I agree with Gross (*Am. Jour. Med. Sciences*) that the skin over the whole breast should be removed. It is here that the recurrences have taken place in all my cases, where any has appeared at all. I feel the importance of this method so much that I am almost inclined to say that in cases where the whole breast is involved, and where enough skin has been left to make a first intention possible, the operation has not been radical enough. I have several cases in mind where there has been long immunity, in which the wound healed by granulations entirely. One of the last cases I saw was found to have cancer infiltration in the skin outside the cut before the patient left the table, shown by fresh section and microscopic examination.

I would not operate in a case where there was infiltration of the skin to any extent, or where glandular infiltration could be detected above the clavicle, or where the axilla was filled with a large adherent mass of glands. Where internal organs are shown to be diseased, or the general condition of the patient is bad, I would not, of course, interfere.

I do not agree with Butlin ("The Operative Treatment of Malignant Disease") as to the partial removal of the breast. Where the microscope has shown the existence of cancer, I would take away the whole of the gland and the skin over it, as well as everything below it down to the pectoral, and, moreover, I would take with the gland the tissues about it, especially on the side next to the tumor.

I feel certain that if we follow this method of selecting the cases, especially, as I said in the introduction, if we incise every lump in the breast as soon as it is discovered, and subject it to the microscope; and when it is malignant, if we follow the method I have been advocating during the past eight years, we shall be able to effect a permanent cure in a much larger percentage than hitherto.

In conclusion, I would say that I believe we are going to operate by improved methods upon cases much earlier discovered and recognized, and more carefully studied, with very much better results. The average operation is going to be more radical, it will be more thorough and more formidable, and more truly conservative, because it will only be performed when its most radical performance promises the greatest good; namely, at the beginning of the disease, and not when the near approach of dissolution has made it, as too often in the past, the most forlorn of forlorn hopes.

REPORT ON PROGRESS IN THORACIC DISEASE.

BY FREDERICK C. SHATTUCK, M.D.

THE TREATMENT OF CHRONIC DISEASE OF THE MUSCULAR TISSUE OF THE HEART.

At the recent Congress for Internal Medicine a session was given to this subject.[1]

Oertel,[2] the referee, strongly advocated his method of treatment of these conditions by limitation of the ingesta, particularly fluids, and systematic exercise. Further experience has simply confirmed his first published opinions. The results claimed by him are summarized as follows:

(1) Invariable success in the later stages of fat-heart, uncomplicated by sclerosis of the coronary arteries, occurring mostly in persons advanced in years with serous plethora, venous stasis, and often œdema.

(2) Restoration of ruptured compensation and compensatory hypertrophy in cases of valvular disease, and impaired pulmonary circulation due to vertebral disease.

(3) Disappearance of marked dilatation of the heart-muscle — so far as it was not compensatory — dependent on weakness of the muscle, and increase of the intracardial pressure in valvular disease.

(4) As far as may be, the restoration of equilibrium between the arterial and venous systems, with relief to cyanosis, serous plethora, and an unduly watery or even œdematous condition of the tissues.

(5) Relief, partial or complete from respiratory symptoms. Further experience is needed to determine the permanency of the gains which result from this treatment. The first case reported by the referee — said, by the way to be his own — proves that the duration may be considerable. It is now thirteen years since treatment was begun, the loss of compensation with serious circulatory disturbances and œdema having existed for a year at that time, and the gain is perfectly maintained to-day. The prognostic value of this case is undeniable.

Lichtheim, the co-referee, thinks that Oertel's claims are excessive. His paper is summarised as follows:

(1) I consider Oertel's method eminently suited to those forms of chronic heart disease arising from immoderate eating and drinking and insufficient bodily exercise.

(2) In those affections, on the other hand, which are traceable to the distending influence of excessive physical exertion, or other cause, Oertel's method is of no avail.

[1] Beilage Zum Centralblatt für Klin. Med., 1888, No. 25.
[2] Vide Report on Progress Journal, 1887. I, p. 203.

In these exertion is only to be allowed when the compensation is tolerable, and it should then be graded. Patients of this sort must be treated much more cautiously than those with valvular disease.

(3) The administration of digitalis, strophanthus and caffein is and remains the proper treatment for impaired compensation; where it fails the dietetico-mechanical does not succeed. Oertel's method may aid the drugs in removing the dropsy, but can never take their place.

(4) As long as the compensation is intact there is no reason to give drugs, except as now and then a symptom calls for interference. This is a period when diet and exercise are in place, and the principles laid down by Oertel, applied with judgment, may do good service. It should be added that Lichtheim is at variance with Oertel also as regards a more theoretical point. The latter believes that the blood is in a watery, dilute condition, in cases of failure of the heart-wall; but the former holds it as demonstrated that in uncompensated heart disease the concentration of the blood is not diminished, nay, that when dropsy is present the concentration may be increased.

Kisch endorsed this observation of the previous speaker, and added that experiments of his own showed that the blood of highly obese persons contains an increased rather than a diminished amount of red corpuscles, and also of hæmoglobin. Oertel's idea that there is in these two classes of cases a serous plethora is, therefore, erroneous. He also agreed with Lichtheim that the chief danger in disease of the muscular structure of the heart lies in stretching the muscle. Microscopic study of the hearts of fat people and of overfed geese have convinced him that fatty degeneration of the heart muscle is long delayed in these cases, and results from the pressure exerted on the bundles of muscular fibres by the growth of fat between them. But, before any degeneration occurs, the efficiency of the cardiac contractions is impaired by the load of fat on and in the wall.

In short, Oertel's treatment is applicable to only a very limited number of cases.

Fræntzel also expressed himself as in agreement with Lichtheim.

Schott (Nauheim) has convinced himself that Oertel's theory of the existence of hydræmic plethora in cardiac cases as the result of increased ingestion of fluid is mistaken. Hill-climbing is a form of exercise much better adapted to the end than the beginning of treatment; for the reason that it is difficult of control and accurate dosage, so to speak.

Riegel finds it incomprehensible that the sweeping statement should be made — and it has been made repeatedly — that the dietetico-mechanical treatment is indicated in valvular disease in general. The different valvular lesions do not call for precisely the same treatment; more discrimination must be exercised than is common.

FATTY DEGENERATION OF THE HEART FROM INTRA-ABDOMINAL PRESSURE.

Bedford Fenwick [3] gives a more detailed analysis of the twenty-two cases coming under his observation. The average duration of the abdominal distension was 22.7 months, the average age of the patients forty-four years. Sixteen of the cases were ovarian, three fibro-cystic of the uterus, two renal, one omental cyst. The diagnosis of the cardiac degeneration rests on: (1) A feeble and diffuse impulse, the sounds being dull at the apex, especially over the right ventricle. (2) A small, feeble and compressible pulse, fast or slow, but unduly accelerated by the slightest exertion, perhaps as much as thirty or forty beats a minute. (3) A tendency to local anæmiæ and local congestions, pallor of the skin, a tendency to faintness, even going on to syncope, and a constant inclination to yawn or sigh, or even a marked condition of dyspnœa, the age of the patient and the duration of the swelling are also to be taken into account.

The prognosis in advanced cases bad. The earlier the affection is recognized, and the sooner the determining cause can be removed, the better the patient's chances. An important practical lesson is not to delay operation too long. If the tumor cannot be removed, the pressure dangers should be prevented by early, and if necessary, by repeated tapping.

MOVEABLE HEART.

Rumpf [4] reports five cases in which the heart, as was shown by the seat of the impulse and the area of dulness, changed its position in the thorax to an unusual degree in accordance with the position of the patient. In the most extreme case, the impulse in the erect posture was 61 to 62 cm. from the left sternal border; in the right lateral position it was just to the left of the sternum; in the left lateral in mid-axilla; the distance between these two extremes was 13 to 14 cm. The symptoms were inability to lie on either side without pain, oppression, and increased rapidity of the heart's action, with weakness, vertigo and partial disablement as regards work. Four of the five patients had either just undergone treatment for corpulence or lost much flesh, a fact which strikes the author as very significant. He propounds the theory that the undue motility is dependent on the loss of fatty tissue from about the organ.

(This explanation seems very fanciful, and one is more inclined to believe that the cardiac symptoms which were present, were due to debility resulting from rapid or excessive loss of weight, than to the shifting position of the heart. But it is well to know that the heart can move within such wide limits.—REP.)

TREATMENT OF CONSUMPTION BY RESIDENCE AT HIGH ALTITUDES.

Dr. C. Theodore Williams [5] offers a contribution from his own practice, of one hundred and forty-one cases of phthisis treated in sanitaria in altitudes from 5,000 to 9,000 feet, in the Alps, the Rocky Mountains and the South African Highlands, during the last nine years, in order to deduce certain practical rules therefrom. The one hundred and forty-one cases have been tabulated for statistical purposes under the following headings: Sex; age; length of illness before the commencement of mountain residence; hæmopytsis; history and nature of cases; state of the lungs; medicine and diet; length of residence at high altitudes. The Alpine climate is then compared with that of Colorado and the South African Highlands. The results of this treatment have been tabulated under the heads of *General;* referring to the general health, vigor, and weight: and *Local;*

[3] Lancet, 1888, I. p. 1067. Vide Report on Progress, Journal, I. p. 246.

[4] Beilage zum Centralblatt für Klin. Med, 1888. No. 25.

[5] Lancet, 1888, I. p. 924.

including the conclusions arrived at from the examination of the lungs. The general results are divided into (1) cured, 41.13 per cent., where the restoration to health was complete; (2) greatly improved, 29.78 per cent.; (3) improved, 11.34 per cent.; deteriorated, 17.02 per cent.: thus giving a total of 82.25 per cent. improved, and 11.34 per cent. deteriorated, including 13.47 per cent. of deaths. The local results of the one hundred and forty-one cases yield improvement, greater or less, in 74.82 per cent., (including arrest in nearly forty-four per cent.), deterioration in nearly 12½ per cent., and a stationary condition in 3.59 per cent. Among the first stage cases there was improvement in 91 per cent., and arrest of disease in 63 per cent., with deterioration in nearly 7½ per cent. Cases of unilateral first stage give 92 per cent. improved, and 70½ per cent. of arrests, and cases of bilateral affection yield 87.09 per cent. of improved, and 48.58 of arrests, and in the second and third stage cases there was improvement to a greater or less extent in 46 per cent., arrest in 10 per cent., and deterioration in 46 per cent. Single cavity cases gave better results than cavity cases with the opposite lung involved, and left lung cavities showed a less tendency to change, either for better or worse, than the right lung ones. The following conclusions are arrived at:

(1) That prolonged residence at high altitudes produces great improvement in the majority of consumptive patients, and complete arrest of the disease in a considerable proportion, such arrests being in a more or less degree permanent. (2) That in order to secure these advantages, patients must be free from pyrexia and all acute symptoms, and must possess sufficient lung surface adequately to carry on the process of respiration in the rarified atmosphere. (3) That the influence of the climate seems to promote a change in the lungs, either of a curative or destructive character, and to oppose quiesence. (4) That residence at high altitudes causes enlargement of the thorax, hypertrophy of the healthy lung tissue, and the development of emphysema around the tubercular lesions, and that this expansion of the chest is accompanied by diminution of the pulse and respiration rate. (5) That it is probable that the arrest of consumptive disease is partly owing to the pressure exercised on the tubercular masses by the increasing bulk of the surrounding tissue. (6) That the above local changes are accompanied by general improvement, shown in the cessation of all symptoms, and the gain of weight, color, and of muscular, respiratory, and circulatory power. (7) That consumptives of both sexes benefit equally by mountain residence, but that the age of the patient exercises considerable influence on the result. (8) That the high-altitude treatment seems to be specially adapted in cases where heredity and family predisposition are present. (9) That the climate is useful in cases of hæmorrhagic phthisis, and that hæmoptysis is of rare occurrence at the mountain stations. (10) That mountain climates are most effective in arresting phthisis when the disease is of recent date, but that they are also beneficial in cases of longer standing. (11) That the special effect of high-altitude residence on the healthy and sick are common to all mountain ranges of elevations of 5,000 feet and upwards. (12) That to ensure the full advantages of high-altitude residence, a period of at least six months is necessary in the majority of consumptives. In cases of long standing and extensive lesions, one or two years are often requisite to produce arrest of the disease. (13) That in addition to the above examples, mountain climates are beneficial in (1) cases of imperfect thoracic and pulmonary development; (2) chronic pneumonia without bronchiectasis; (3) chronic pleurisy where the lung does not expand after removal of the fluid; (4) spasmodic asthma, without much emphysema; and (5) anæmia. (14) That they are contra-indicated in the following conditions: (1) phthisis with double cavities, with or without pyrexia; (2) cases of phthisis where the pulmonary area at low levels hardly suffices for respiratory purposes; (3) catarrhal phthisis; (4) erethitic phthisis, or phthisis where there is great irritability of the nervous system; (5) emphysema; (6) chronic bronchitis and bronchiectasis; (7) diseases of the heart and greater vessels; (8) affections of the brain and spinal cord, and conditions of hypersensibility of the nervous system; and (9) where the patients are of advanced age, and where they are too feeble to take exercise.

Dr. Hermann Weber gave a few of the results of his own statistics of 106 cases treated at high altitudes. Of these 38 were cured, 28 improved, 16 stationary, and 10 deteriorated. Of 70 in the first stage, 36 were cured, 28 improved, 11 stationary, and 6 grew worse. Of 32 in the second stage, 2 were cured, 13 improved, 11 stationary, and 6 deteriorated. Of 4 in the third stage, 1 was improved, 1 remained stationary, and 2 deteriorated. Whilst granting that high altitudes did thus effect great good, Dr. Weber pointed out that equally good results might be obtained at lower levels if systematic medical and dietetic treatment were carried out at Falkenstein, near Frankfort. From this place, which is only about two thousand feet above the sea level, Dettweiler's statistics (which are perfectly reliable) prove this contention. In Dr. Weber's cases the gain in weight was observed in 58 cases; weight remained stationary in 40, and 8 lost flesh. It was remarked, however, that patients could be well nourished before being sent to high altitudes, so that a gain in weight might thus be anticipated by previous treatment.

Drs. Pollock and Quain criticised Dr. Williams's paper, and maintained that equally good results could be, and, in fact, were obtained by medical and hygienic treatment in London. It is precisely those cases that are benefitted at high altitudes that do well at home.

Drs. Tucker, Wise, Ewart, and Huggard spoke in favor of high altitudes.

Drs. De Haviland, Hall, and Williams agreed that cases of laryngeal phthisis do badly in the mountains, and the latter argued that at home, or on sea-voyages, or in warm places, good results could be obtained, yet that high altitudes yield far better results. This was shown in the actual arrest of the disease, which did not happen, or very rarely, when cases were treated elsewhere. By arrest he meant total disappearance of all physical signs of lung mischief, as well as restoration of the constitutional state.

PNEUMO-HYDRO-THORAX TREATED BY INJECTION OF STERILIZED AIR INTO THE CHEST.

Potain[6] reports three cases of pleural effusion consecutive to pneumothorax of tubercular origin successfully treated by injection of sterilized air into the pleural cavity by the following method: A needle

[6] Bull. de l'Acad. de Med., 1888, No. 17.

similar to that of a hypodermic syringe, attached by a fine rubber tube to a reservoir of air which has been sterilized by being passed through a strong carbolic solution and then through cotton, is introduced into the sixth intercostal space while the trocar of an aspirator is plunged into the seventh. The air is then allowed to flow in as rapidly as the fluid escapes, its flow being regulated by means of a clip on the tubing so as to maintain about a normal intrapleural pressure of 6 to 7 millimeters of mercury, as shown by the small metallic manometer attached to the aspirating apparatus. At each operation all the fluid was withdrawn, and it was repeated as often as the chest refilled, in one case four, in another five times. It was attended by no discomfort apart from the introduction of the needles, and was followed by great relief from all urgent symptoms. The final results were eminently successful; in all three cases the pneumothorax was cured without retraction of the chest, and in two the phthisical process was arrested. In the third case both lungs were affected, and the disease, which seemed checked for a time, went on to a fatal termination. The method is only applicable when the effusion is serous or sero-purulent, and not fetid, and should be deferred till the fluid has become either inconvenient from its weight or dangerous from its volume. It is contraindicated when there is a large communication with a bronchus, or the effusion is fetid. The advantages of the operation are that the dangers from a large quantity of fluid in the pleural cavity are avoided, as well as those arising from rapid evacuation of a large effusion; that the serious inconveniences of frequently repeated punctures are avoided, escaped, and the lung is allowed the possibility of slow and progressive expansion. Finally, cicatrization and cure of tubercular lesions seem to be favored by keeping the affected lung for a long time at rest.

EMPYEMA AFTER FIBRINOUS PNEUMONIA.

Penzoldt[7] is led to believe that this accident is commoner than is usually supposed, as he has recently seen seven cases. The course of the pneumonia in all the cases was severe, and the temperature failed to return to normal at the time the local symptoms indicated the crisis. This sign, however, often fails, and no other symptom indicates the presence of pus. He, therefore, urges the importance of exploratory puncture in all cases where dulness and bronchial respiration persist, with fever and diminution of strength. He has, by neglect of this in the past few years, failed to discover the existence of empyema after pneumonia, or has found it too late in a few cases. It seems probable to him that in these cases the active infectious germs producing pneumonia and those causing pus are associated, the latter finding their way into the pulmonary pleura.

Hood,[8] in order to emphasize the difficulty of distinguishing between pleuritic effusion and solidified lung by physical signs, reports four cases of empyema following pneumonia, together with a fifth case, cause not stated, where the differential diagnosis was made by puncture. In two of the cases, granting the presence of fluid, there was no evidence of its purulent character. Hectic, sweats, and fluctuating temperature were wanting. In one case the temperature was 99°, in another normal at the time of aspiration.

Hospital Practice and Clinical Memoranda.

BOSTON CITY HOSPITAL.

DISLOCATION OF HIP OF ELEVEN MONTHS' STANDING; REDUCTION BY MANIPULATION.

SERVICE OF DR. W. H. THORNDIKE.

REPORTED BY D. E. BAKER, M.D., *Former House Surgeon.*

The following case has been deemed worthy of publication on account of the circumstances attending the accident, the different views entertained as to its nature and the length of time that elapsed before relief was obtained.

Mrs. M., a widow, nineteen years of age, entered the hospital September 14, 1883. In October of the previous year she had been confined, and eight days afterward left his bed and moved about the room. Three weeks after labor she began to have pain in the left knee, which later shifted to other parts of the body. In the course of another fortnight the pain had settled in the left thigh and increased in intensity. No constitutional symptoms had thus far appeared.

While lying on the sofa on the 25th of October, 1882, she felt severe pain in left hip and down the back of the thigh, which was far more acute than had been previously experienced. On attempting to get up and walk the left leg gave way under her, and she fell to the floor, but was unable to tell how she struck. She was lifted into a chair, and from the chair carried to the bed, where she first noticed a tendency in the left knee to fall in and overlap its fellow. There was great pain behind and above the hip joint of that side when she attempted to rest on the left natis. The only relief obtained was by keeping the leg flexed and supported on a box under the knee, and the subcutaneous use of morphia every four hours. Chills, high temperatures and profuse perspirations ensued. For eleven weeks she was kept under the influence of morphia much of the time. This was abandoned on account of its unpleasant effects. At the end of thirteen weeks she began to sit up, and a month later to go on crutches, with the limb flexed and the toe far from touching the floor. When she was beginning to get about there was an examination made under ether, and the opinion was expressed that the hip was out of joint, but no decided efforts were made to restore the bone to its place. For three weeks imperfect methods of extension were employed, such as suspending a weight from the foot over the end of the mattress when she was in bed, and allowing a weight to dangle from the left foot while she supported herself between two chairs in the erect position. One of her medical attendants had treated her for sciatica, and another for possible hip disease. The foot gradually came down so that at length the great toe rested on the ground, and the limb was used in walking. Two months before entering the hospital she dispensed with one crutch. The appetite had been poor, and the strength was easily exhausted, until the last three weeks before admission, when she made some gain in these respects, and could walk three-fourths of a mile with but one crutch. The patient stated that she realized the severity of the operation to reduce the dislocation, but could not feel satisfied until the attempt had been made.

In the examination that followed her entrance into the hospital, it was found that in the erect posture the toes and ball of the left foot touched the floor. When lying on her back the left knee overlapped the right, and the left foot was inverted, the great toe overriding the opposite instep. The thigh could be slightly flexed without moving the pelvis, but flexion beyond a certain point tilted the pelvis and caused pain. The distance from the anterior superior iliac spine to the patella was one inch shorter on the left than on the right side. A straight line from left anterior superior iliac spine to left internal malleolus passed outside the patella. The left internal malleolus was apparently two and one-half inches above the right. The tip of great trochanter on this side was one inch above Nelaton's line, and the same point was an inch farther from the anterior superior spina ilii on the left than on the right side. The head of the femur could be plainly felt on the dorsum ilii far back of the acetabulum. Under ether, with the leg fully extended, the line from the left anterior superior spine of the ilium to left internal malleolus passed over the patella, and was one inch shorter than the corresponding distance on the right. The muscles were smaller on the left side than on the right. Grating was felt during the flexion of the thigh under ether.

In consultation, the surgical staff confirmed the diagnosis and advised the attempt at reduction. Accordingly, on September 21st, one week after admission, the patient was etherized for this purpose. While the pelvis was steadied by the hands of the assistants, Dr. W. H. Thorndike performed the manipulation. The thigh was flexed, adducted, circumducted outward, and rotated, and the manœuvre repeated twice, when a marked thug was perceived, after which the leg was lowered to the table. On raising the leg the head of the bone appeared to be somewhat below the joint, whereupon the operator placed his arm under the knee, with the thigh slightly abducted, and forcibly jerked the latter upward, when a second thug was detected, and the normal movements of the limb could then be performed without any resistance.

A mass of indurated tissue was found behind and above the acetabulum, where the head had rested, but the marked prominence of the latter had disappeared. With the limbs extended, the patellæ were opposite, but semiflexion of the thighs made the left femur appear about one inch shorter than its companion. This might be accounted for by the smaller glutei of the left side, an original difference in length of the femora, or by absorption of the left cervix femoris. In flexing the thigh on the pelvis, the head grated somewhat in its new, but old position. Measuring from the ilium to the patella, one-fourth inch shortening was obtained, but between the ilium and malleolus no disparity was demonstrated.

The knees of the patient were bound together and morphia given subcutaneously during a paroxysm of pain, which occurred during the first night after the operation. She slept between two and three hours. In twenty-four there was marked ecchymosis, swelling, and tenderness of the thigh and intermittent pain. For the next few days laudanum fomentations were applied about the hip and thigh, and the ankles and knees were bound together.

The temperature fluctuated between 99° F. to 102° F. for three days, and the pulse from 100 to 120, then gradually both declined. Patient slept fairly well, but suffered from paroxysmal pain, and evinced considerable nervousness, with twitching of eyelids and mouth. A week after the reduction the legs could be flexed to an angle of 45° without much pain to the patient. The ankles and knees were then unbound and a lateral decubitus allowed. In a fortnight there was but little tenderness, swelling and discoloration had disappeared, and the thickening behind the acetabulum was not so apparent. Rotation of the thighs gave a sense of difference in the length of the two femoral necks. The patient sat up October 5th, and brought a part of her weight on the left foot, the heel resting on the floor. For another fortnight more or less pain occurred, which was relieved by fomentations and a blister, two inches square, in front of the joint. Walking about on crutches, she gathered strength daily, and the gait was even, but slightly limping. She took four minims of Fowler's solution and three grains of quinia thrice daily. At the expiration of a month she could walk without crutches by taking the hand of her nurse, but this gave her considerable pain. She left the Hospital November 9th, able to hobble about without crutches, or to walk evenly with them, and in good general health. The subsequent improvement was rapid and recovery complete.

Three years after the operation she writes that her health was never better, and that the hip is all right. The limb is a trifle short, but there is no limping to speak of, and the only pain is a slight rheumatism if she gets cold.

Reports of Societies.

ESSEX NORTH DISTRICT MEDICAL SOCIETY.

THE Annual Meeting was held at Haverhill, May 2d, the president, DR. E. P. HURD, in the chair.

The following officers were elected for the ensuing year:

President, Dr. C. G. Carleton, Lawrence. *Vice President*, Dr. G. W. Snow, Newburyport. *Secretary and Treasurer*, Dr. Maurice D. Clarke, Haverhill. *Corresponding Secretary*, Dr. Aug. Stabler, Lawrence. *Censors*, Drs. J. F. Young, Newburyport; R. C. Huse, Georgetown; F. W. Kennedy, Lawrence; J. F. Croston, Haverhill; H. F. Adams, Newburyport. *Councillors*, Drs. John Crowell, Haverhill; George Montgomery, Newburyport; F. A. Howe, Newburyport; L. J. Young, Haverhill; C. N. Chamberlain, Lawrence; R. B. Root, Georgetown; J. A. Douglass, Amesbury; O. Warren, West Newbury; C. P. Morrill, North Andover. *Commissioner of Trials*, Dr. F. A. Howe, Newburyport. *Nominating Councillor*, Dr. John Crowell, Haverhill.

DR. SUSAN E. CROCKER, of Lawrence, read a paper on

FOOD POISONING.

After introductory remarks on the methods of development of poisonous alkaloids from food in daily use, the following case was cited to show how a most potent poison was developed under quite ordinary circumstances:

On the 25th of last July I was called to see a family consisting of father, mother and one child. On my arrival I found that Mr. H., who had just reached home, was sitting on the sofa, wrapped in blankets and shivering with cold, a striking picture of collapse.

His face was pale, cyanotic, eyes and cheeks sunken, pulse scarcely perceptible. The wife was throwing herself about in paroxysms of pain and agony. Retching, vomiting and profuse diarrhœa were marked symptoms. The daughter, five years old, presented the same symptoms in a less aggravated form. I found that all were attacked about two hours after the noon meal, of which all had partaken together. Mr. H. was taken with severe gastric and abdominal pains soon after leaving Lawrence for Boston, quickly followed by vomiting, purging and great prostration. He was so weak before reaching the city that he had to be assisted from the car to the waiting room, where he remained in great agony until the next train for Lawrence.

Mrs. H. and the child developed similar symptoms about the same time, but in a less alarming degree, domestic remedies giving temporary alleviation, only to be followed by a renewal of the symptoms of poisoning.

Mrs. H. and the little girl were soon made comfortable, but Mr. H.'s symptoms continued to be alarming for several days. Chills, vomiting, and copious intestinal discharges continued until the next morning, when they became less frequent. These discharges were thin, and contained blood, mucous and membranous shreds. During the day Mr. H. rallied somewhat, and was able to take a small quantity of champagne. The pulse, which had been feeble and intermittent, grew stronger, and from that time improvement took place.

The treatment presented nothing of note, being directed mainly to a treatment of symptoms, and, in the case of Mr. H., to a prevention of fatal collapse, which seemed imminent.

In all these cases blood was seen in the discharges, being least in that of the child, and very large quantity in Mr. H.'s case. The pain and vomiting were greater in Mrs. H.'s case than in that of her husband, but the prostration was not so marked, and the rallies much sooner.

As soon as possible after making the family comfortable, I proceeded to investigate the cause of trouble. I inquired particularly about every article eaten at dinner. This meal consisted of bread, potatoes, salt fish and cream pie. All had partaken of these articles. In addition the little girl had eaten a few berries. I was able, very soon, to eliminate the bread, potatoes and salt fish. For obvious reasons these could not have been the source of the trouble. Neither could the berries have been at fault, as only one had eaten of them. The cream pie alone remained, and of this all had eaten. Inquiring more particularly about this pie, I found that it was cooked the day before, and formed a part of the dinner of that day, and all had eaten more abundantly of it than the second day, as less than a fourth remained over from the first dinner. This showed conclusively that if there was poison in the cream pie it had been developed in the twenty-four hours between the two dinners. None of the pie remained for examination.

I found, moreover, that the father had eaten the largest portion, the mother the next larger, while the child had barely tasted of it, hence the lightness of the attack in her case.

Cream pie is a compound of eggs, milk, corn-starch and sugar. To these ingredients is usually added some flavoring. Vanilla is the favorite extract used, and this was the flavoring used on this occasion. In some similar cases of poisoning vanilla has been charged with being the toxic agent, but in this case the vanilla had been in the house for some time, and had been proved perfectly harmless.

The next question was where and how was the pie kept? The family had been out of town, and were intending soon to go out of town again, and had not thought it necessary to take ice for the short time that they remained at home. They had, therefore, placed several perishable articles in the cellarway to keep cool, the cream pie with the rest. In this cellarway I found the three conditions most favorable to cryptogamic growth, warmth, moisture and darkness. The air in the cellar, it is true, was cooler than the external air, but as there had been a long period of continued high temperature the cellar air was of a much higher temperature than usual.

It is evident that some chemical change took place in the pie, whereby an irritant poison was developed, and in view of the part which microbes are known to play in inducing such chemical action, we may conclude that the germs living in the close air of the cellar were the primary cause of this action. The stagnant air of the cellar, the heat developed by many days of continuous high temperature, the moisture at just the right point to favor the development of germs, formed, indeed, a most favorable state of things for producing the result described.

The case of cream pie poisoning cited is not unique. At least one other case occurred in Lawrence last summer, in which a husband and wife were the victims, and in which cream pie, kept over from the previous day's dinner, was the toxic agent. In the latter case the pie was shut up in a closet, without ice, under somewhat similar conditions.

After speaking of some varieties of microbes, and their agency in producing ptomaines, the speaker referred to the many cases of ice cream poisoning published in the periodicals of the day, showing that the cause was undoubtedly the same as in that of the cream pie cases mentioned. The studies and experiments of Professor Vaughn, and his discovery of tyrotoxicon throw much light on the *modus operandi* of the cases cited, and some of his experiments were detailed at some length. His latest report was especially interesting, describing as it does the history of four cases of poisoning in one family, three of which proved fatal. The poison was, by careful tests, traced to some milk kept in a pantry under conditions favorable to germ growth, and the ptomaine was found to be tyrotoxicon.

In view of the many cases of poisoning occurring every summer, the many cases of cholera morbus, which might, if carefully traced, be found to be caused by some food in which tyrotoxicon or other ptomaine exists; in view of the fact that cholera infantum is probably caused in many cases by the presence of poisonous ptomaines in the milk given to the child, it is urged upon physicians to carefully investigate such cases occurring in their practice, to the end that the conditions under which such ptomaines are produced may be better known.

Dr. Carleton related the case of a family poisoned by cream pie, similar to Dr. Crocker's case.

Dr. A. Howe, of Newburyport, had seen a family with similar symptoms that had eaten of stale cream pie.

DR. J. J. HEALY, of Newburyport, had seen a family with like symptoms, and had traced the poisoning to oatmeal porridge that had been kept over twenty-four hours.

DR. C. E. DURANT, of Haverhill, read a paper on

ABORTION.

He advocated active interference to evacuate the uterus of any portion of the placenta or membranes be retained.

Remarks were made upon the paper by Drs. Flanders, R. C. Huse and Stabler.

DR. STABLER advocated the use of opium in full doses in threatened abortion wherever there is reason to hope that a child may be saved. It quiets the contractions of the uterus, and for this purpose he thinks opium a better drug than morphia.

DR. HUSE agreed with Dr. Stabler with regard to the value of opium. He has seen cases where morphia produced more vomiting than opium, and thinks it may be due to the presence of apomorphia as an impurity.

DR. JOHN CROWELL, as chairman of a committee to draw up a memorial of Dr. Nichols, read the following:

IN MEMORIAM JAMES R. NICHOLS, M.D.

James Robinson Nichols, a member of this Society since 1857, was born in West Amesbury (now Merrimac) July 18, 1819. In early life he came to Haverhill as a clerk in a drug store, and, being of an inquisitive turn of mind, he became interested in mechanical invention, and his spare hours were spent in the construction of many ingenious appliances. He commenced the study of medicine under the preceptorship of Dr. Kendall Flint, and, with scanty pecuniary means but with a persistent purpose, he attended a course of medical lectures at Dartmouth College in 1842, but, changing his purpose in the choice of a profession, he did not graduate, although he subsequently received the degree of M.D., and, later, that of A.M., from that institute.

In 1843 he established a drug store in Haverhill, where he did a thriving business, devoting his leisure hours to the study of theoretical and practical chemistry, and to numerous mechanical inventions, many of which are still widely in use. In 1856 he had the advantage of an extended European tour, and in 1857 he established in Boston the house of J. R. Nichols & Co. for the manufacture of chemical and medicinal preparations. This establishment has had a large pecuniary success and an honorable reputation.

Dr. Nichols was a voluminous writer upon subjects related to his favorite work; and through the medium of the *Journal of Chemistry* (now the *Popular Science News*) established by him, his articles upon popular Scientific topics and psycological speculation and investigation have attained a wide circulation. Several of his literary works have found more substantial form in the volumes published by him upon the processes of cultivation of the soil and the operation of the forces of nature in the common ways of life. The book entitled "Whence, What, Where?" written in 1882, is the best known of his literary publications. This work, written in an attractive style, furnished perhaps the best illustration of the modes of thought of the writer in the realm of material and psychical investigation, speculation and reverie.

In social life Dr. Nichols had the elements of delightful companionship. His fertile mind, his wide observation and extensive reading made him a rare conversationalist, and no one could long be in his company without receiving valuable information and suggestion. His abundant wealth enabled him to dispense a generous hospitality, and the members of this Society have often enjoyed a social hour amid the delightful haunts of Kenoza and Winnikeni.

Although not a practicing physician, Dr. Nichols was deeply interested in our profession, and during the early years of his membership he gave many valuable lectures to this Society upon experimental chemistry and other subjects connected with medical science.

For many years he was an invalid, suffering much from indigestion and consequent nervous depression and insomnia; and finally, on January 2, 1888, his physical forces succumbed to the power of disease, and he passed peacefully into rest.

. . . . "And when the stream
Which overflowed the soul was passed away,
A consciousness remained, which it had left
Deposited upon the silent shore
Of memory, images and precious thoughts,
That shall not die and cannot be destroyed."

JOHN CROWELL,
OLIVER S. LOVEJOY,
MAURICE D. CLARKE, } *Committee.*

The Censors reported Dr. Kate Campbell Hurd, of Newburyport, admitted a fellow of the Society.

Recent Literature.

On the Operative Surgery of Malignant Disease. By HENRY T. BUTLIN, F.R.C.S., Assistant Surgeon and Demonstrator of Surgery, St. Bartholomew's Hospital; Late Erasmus Wilson Professor of Pathology to the Royal College of Surgeons. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut Street. 1887.

Mr. Butlin has in this work really conferred a favor on the practical surgeon of to-day in that he has concisely formulated the knowledge on this subject in an admirable manner. He has written the work hoping to attain one or all of the following ends: "Indicate the class of cases and the parts of the body which may be treated by operative means with the best prospects of success. Encourage the performance of operations in suitable cases at the earliest possible period. Discourage the repetition of useless and dangerous operations. Raise the question of the propriety of the removal of entire organs for the cure of cancer of limited extent." All of the foregoing headings are carefully considered. The book is an admirable one for reference, for its composition is largely statistical. The work is written in an attractive style, the author presenting the information in a judicial manner, carefully weighing the evidence for and against a given operation, and giving the reader the result of his conclusions in a particularly unbiassed manner. Particular attention is called to the practice, so much in vogue, of removing the whole of an organ, as for instance the breast, regardless of the extent of the malignant disease; this procedure is condemned by the author who advises a very free removal of only the diseased structures. It is an excellent work and fills the intended niche.

— The name of the *Canada Medical and Surgical Journal* has been changed to the *Montreal Medical Journal*. It has been enlarged in size from sixty-four to eighty pages, at the same time reducing the subscription to two dollars per annum, and making other improvements that, it is hoped, will place it in the front rank of medical publications.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 6, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

DENSITY OF POPULATION AS A SOCIAL AND SANITARY QUESTION.

THE laborious work of the statistician often lies buried for years, until some intelligent thinker brings it to light and makes a practical application of the data thus collected. John Bright once said in a public assembly, "I find it stated that in Glasgow alone 41 families out of every 100 live in houses (tenements) having only one room." He was immediately interrupted by his audience with shouts of incredulous laughter, whereupon he replied, "That is the official statement of the census." This was said with reference to the census of 1871, and was a good illustration of the proverb that one-half of the world does not know how the other half lives.

In the United States, with the exception of a few large cities, we know but little of the conditions which prevail in European cities with reference to the amount of space occupied by the population.

In the 45th Registration Report of Massachusetts, (1886) a table was presented in which was given the density of the population of the State as a whole, and that of the manufacturing counties, as compared with that of the agricultural or rural counties. With the exception of Rhode Island, Massachusetts is the most densely populated State in the Union, and has by its last census a population of 233 to the square mile. In the six manufacturing or urban counties containing nineteen of the twenty-three cities of the State, the density amounted to 442 persons to the square mile, while in the eight agricultural counties the average density was scarcely 100 per square mile. The death-rate of the former was 19.7 per 1000, of the living population, and of the latter it was but 17.7 per 1000.

This slight difference in percentage appears at first sight insignificant, but when applied to the two million inhabitants of the State, a difference of two deaths only per 1000 means an excess of almost 4000 deaths, for the higher death-rate.

If different periods are contrasted, as for example, the five years ending with 1854, with the five years ending with 1886, in which time the population had nearly doubled, and the density increased from 120 to 233 to the square mile, the death-rate had also increased from 18.4 in the former to 19.5 per 1000 in the latter period, a difference of 1.1 per 1000. These differences are chiefly manifested in the cities, since it is only in comparatively crowded populations that this principle finds application.

Another illustration of the same principle having a sanitary bearing is found in the adulteration of certain common articles of food. The reports of the State Board of Health showed that in the four western counties of Massachusetts, having a population with an average density of 95 per square mile (census of 1885) milk adulteration is practically unknown, while in the four counties of Suffolk, Middlesex, Essex and Norfolk with a density of 582 per square mile, the greatest vigilance is constantly required for its prevention.

In two recent essays entitled "The House in its relation to Public Health" [1] and Life in One Room," [2] Dr. J. B. Russell has given some instructive statements as to the crowded condition of tenement-house life in Glasgow, from which he deduces certain propositions which are of special value to sanitarians, in consequence of the clearness and forcible manner in which they are stated.

By the census of 1881 Glasgow had a population of 511,520; of this number nearly 25 per cent. or 126,000 lived in tenements of one room and 228,000 or 45 per cent. in two-roomed houses. In commenting upon this fact, Dr. Russell says to his audience, "Percentages though accurate, are but a feeble mode of expression of facts regarding men and women like ourselves. I might throw down that statement before you, and ask you to imagine yourselves with all your appetites and passions, your bodily necessities and functions, your feelings of modesty, your sense of propriety, your births, your sicknesses, your deaths, your children, in short your *lives* in the whole round of their relationship with the seen and the unseen, suddenly shrivelled and shrunk into such conditions of space. Where can I find language in which to clothe the facts of these poor people's lives and yet be tolerable?"

"It is these small houses which produce the high death-rate of Glasgow. It is these small houses which give to that death-rate the striking characteristics of an enormous proportion of deaths in childhood, and of deaths from diseases of the lungs at all ages. Their exhausted air and poor and perverse feeding fill our streets with bandy-legged children. There you will find year after year a death-rate of 38 per 1,000, while in the districts with larger houses it is only 16 or 17. Of all the children who die in Glasgow before they complete their fifth year thirty-two per cent. die in houses of one apartment, and not two per cent. in houses of five apartments and upward. There they die, and their little bodies are laid on a table or on the

[1] Glasgow, 1887. From transactions of the Insurance and Actuarial Society.
[2] Glasgow, 1888. Lecture before Park Parish Institute.

dresser, so as to be somewhat out of the way of their brothers and sisters, who play and sleep and eat in their ghastly company. From beginning to rapid ending the lives of these children are short parts in a continuous tragedy. A large proportion enter life by the wide door of illegitimacy. One in every five of all who are born there never see the end of their first year. Of those who so prematurely die, a third have never been seen in their sickness by any doctor."

It is this factor of space, "in which we live and move and have our being," and the proportion of the numbers in which we live in it, that determine the proportion in which we share the prime physical conditions of health: air, sunlight, earth-space sufficient to give free play to those operations of nature which will keep our environment healthy, if they are not overtaxed by the aggregation of men.

From the data furnished by the vital statistics of England, Dr. Farr constructed a physical basis, and proved that the apparently confused local phenomena of mortality were subjected to certain laws capable of exact numerical expression, and of reduction to mathematical formulæ. A theoretical standard of health was established, toward which the practice of sanitary science could work on precise lines.

The terminology of the new science was expressed in the terms *density*, *areality* and *proximity*. *Density* refers to the number of persons per unit of area on which they live. *Areality* is the unit of area per person living on that area, and is, therefore, the reciprocal of the density. *Proximity* is a function of the areality, and it varies as the square root of the areality. And all these are based on the hypothesis of an equal distribution of the population.

In seven districts in England in 1871 the mortality-rates were respectively 17, 19, 22, 25, 28, 32 and 39 per 1,000. In the same districts the number of persons to a square mile were also 166, 186, 379, 1,718, 4,499, 12,357 and 65,823.

This series of facts may be stated differently. The nearer people live to each other the shorter their lives are. In districts where the proximity averaged 147 yards the mean duration of life was fifty-one years. In districts where the proximity was 97 yards the mean duration of life was forty years; where it was 28 yards the mean duration was thirty-two years; and in Liverpool, having the greatest density and the least proximity, namely 7 yards, the mean duration of life was but twenty-six years.

This law, however, must be applied with a clear understanding of the conditions in which the population lives. The basement of the law is this, that animal life contaminates its environments. In the process of living man defiles air, earth and water. This defilement only becomes dangerous when his environment cannot cleanse itself.

The disadvantage of close proximity finds a typical illustration in infectious diseases. Infection, which means the passage of a material something from person to person, takes place in proportion to the average proximity of the population. If, in one city, the average proximity is eight yards, and in another ten yards, then the chances favorable to infection in the former must be greater than those in the latter, unless by greater care in the treatment of cases of infectious disease such chances are diminished.

It follows (1) that proximity does not begin to tell against health and life until it has passed a certain point; (2) that the same degree of proximity under different circumstances will have different degrees of injurious influence.

From his observations, Dr. Russell deduces the following conclusions:

(1) *The unit room in large houses has a higher cubic value than the unit room in small houses.*

(2) *The smaller the house, as measured by rooms, the greater the number of inmates per room, and, vice versâ, the larger the house as measured by rooms, the fewer the number of inmates per room.*

(3) *The smaller the house, the less the cubic space per inmate, and, vice versâ, the larger the house, the greater the cubic space per inmate.*

(4) *Space is a commodity which is used only as a necessity of life by the wage-earning classes, but is used as a luxury by the wealthy.*

Some of the conditions requisite to secure the wholesome occupation of tenements are the following: They must be carefully planned and built. They must start with the best practicable structural arrangements and sanitary provisions. Their contained air must be put in the best attainable circumstances, both as to renewal, and as to reducing contamination to a minimum by efficient drainage, water-supply, and the removal of refuse. When originally well ordered, the tenement-house must, when occupied, be carefully maintained. It works like an engine driven to the full extent of its horse-power. It is always bursting with life, from roof-tree to foundation. Every part of its movable working apparatus, and even its solid structure, is under strain.

Supposing the structure and maintenance to be perfect, the mode of occupation must be regulated. The condition of wholesomeness lies essentially in the due proportioning of inmates to cubic space. The houses are in the market, but health is at stake in the choice made by the buyers. Every tenant, in making his selection, has on the one side of a line drawn by the laws of the universe, health, and on the other, disease. Experience proves that the occupants of small houses cannot be left to their freedom of action in this matter. There is a moral responsibility on the landlord in the first place, and, failing him, upon the authorities somehow to direct and determine their choice. Supposing this difficulty overcome, the tenement thus properly built, maintained, and occupied, cannot then be left without supervision as to its occupancy. Physical and moral chaos will gradually invade the original order, if an eye, either that of the landlord or of the sanitary inspector, is not kept upon the householders to prevent overcrowding.

The practical application of these pungent words from Dr. Russell to our urban population is plain. The laws relating to tenement-houses are yearly being made more and more stringent and definite in their provisions as to the important questions of ventilation, air-space, drainage, and fire-protection. It remains for local authorities to provide efficient means for the enforcement of the statutes for the protection of the lives and health of the inhabiting population.

YELLOW FEVER IN FLORIDA.

PREVIOUS to the present year, the last general epidemic of yellow fever in the South to reach serious proportions was in 1878 and 1879. New Orleans, the key to the whole Mississippi Valley, was in former years exposed to a standing menace through her trade, especially in coffee, with Rio de Janeiro and other South American ports. Quarantine against the invader served to harass her commerce, but not to exclude the disease. Of late, maritime sanitation has been substituted for quarantine as the effective agency for warding off the fever, and with the most satisfactory results. Memphis, whose growth and material prospects were so nearly ruined by the epidemic of 1878, losing by death, as she did in that year, nearly one-third of her whole population, took to heart the terrible lesson, and despite the demoralization, both sanitary and financial, in which she was left by the scourge, so energetically applied herself to sanitary reform that, when the disease reappeared the next year, it was much less fatal, and there has been no considerable outbreak since.

During the summer of 1887 yellow fever prevailed quite extensively in the Gulf ports of Florida, having been brought into Tampa May 20th, and soon after appearing at Plant City and Manatee. The epidemic, during all these months, seems to have been treated almost entirely by denying its existence. With the approach of cold weather, the disease dropped out of public attention, and the stream of Northern travel was larger than ever. But the disease was continued throughout the winter by a chain of sporadic cases along the line of the South Florida Railway, and Plant City, Tampa, and even Sanford contained undoubted cases of yellow fever during the height of the influx of Northern visitors into the State. The hotel and transportation interest was strong enough to conceal these cases for awhile, even from the United States Marine Hospital Service, though the bulletins finally published by that Bureau in April last bore date, some of them, at least two months earlier than that time. Since the hot season opened, these dormant foci of disease have broken out into active epidemics, and points which are most frequented by winter tourists have also severely suffered.

The city of Havana, which is probably never free from yellow fever, is in close connection with Key West and Tampa, a line of steamers to those points forming by far the shortest and most direct route from Cuba to the United States. There is no ground for present hope that the sanitary condition of that city is likely to be made right. President Grant's scheme for the acquisition of some of the West India Islands may or may not have been good statesmanship, but there is little doubt that United States control of Cuba would enable sanitary measures to be carried out which would be a great protection to the ports commercially in close relation to it. But, in the absence of such control of the infecting focus, the only safe reliance is upon the policy which has been so effective in Louisiana and Tennessee.

That policy, unfortunately, has been too long delayed. Months of concealment, prompted by greed of gain, have allowed the disease to gain a terrible impetus, and, even after it had fastened upon Jacksonville with a violence that swept away all attempts at further denial, instead of employing cleanliness and disinfectants, means of tested efficiency, time was lost in resorting to such things as cannon-firing, in the hope of killing the fever germs by aërial concussion! Jacksonville looks, so far as concerns its streets, at least to the casual eye of the winter traveller, reasonably clean and well kept. It could not have been nearly the undertaking to put it in good sanitary order that it was in the case of New Orleans and Memphis. Corrosive sublimate, and not gunpowder, was needed. The latter savors of voodooism and the beating of the tom-tom.

Up to the middle of last week, the daily list of new cases in Jacksonville does not exceed twelve or fifteen, but the disease took a fresh start at that time, and the daily average since then has more than doubled. The type thus far has been comparatively mild, there being only thirty-seven deaths out of a total (on the fourth inst.) three hundred and thirty-eight cases. This latter figure probably does not represent the actual prevalence of the disease, as some physicians even now are not reporting their cases, professing to fear the disastrous moral effect upon their patients of seeing the yellow flag displayed. We regret to notice that some of the local physicians have fallen victims to the disease. They, as well as the clergymen of the city, have, for the most part, stood manfully in their places. The board of health will, it is expected, call for further medical aid, and many excellent physicians from outside the State are said to be in readiness to respond. Trained nurses are, however, greatly needed, and seem to be difficult to obtain.

Jacksonville though not necessarily the gate-way into Florida, is practically so, and the occurrence of the fever this autumn will doubtless keep away many of the travellers who are wont to turn southward as the days grow shorter. A great deal of money is invested in hotel property and villas in Florida, and some of this property, we fear, will not yield its usual returns this year. It is the old story that "honesty is the best policy." If the disease had been acknowledged, faced

and fought last year, the coming season might have been as fruitful as any, to railroad and real-estate interests.

Refugees from Florida towns have been mostly quarantined from places on the railroad line north. Murphy, N. C., is the only place which has formally opened its doors to the fugitives. Two hundred cheap barrack-huts have been authorized to be built at Jacksonville for the negroes who are liable to propagate the fever, and who will be removed thither. The refugee camp, located on high pine land on the south bend of the St. Mary's River, on a site selected by Dr. Guiteras, is in one of the healthiest parts of Florida, and it has been abundantly supplied with tents and supplies by government. A number of tents have been set apart, about a quarter of a mile from the rest, for "suspects." Temporary quarantine stations have been established by the Marine Hospital Service near Way Cross, Ga., and Live Oak, Fla., where all northbound travellers are inspected, and unless they can show that they come from a point known to be free from the disease, they are returned at their option either to their original point of embarkation or to "Camp Perry," where they are kept for ten days before being allowed to go to their destination. The residents of Jacksonville express great indignation that they are not allowed to go through to the North, but they are kept to the refugee camp, except such as go to Murphy or other definite points on parole not to go to the seaboard or to any quarantined points within ten days after leaving Jacksonville. Very few cases of disease have passed beyond the State line. One case of yellow fever is reported to have been treated in one of the Philadelphia hospitals. We learn that since 1871 there have been but four deaths from the disease in Boston, all occurring at quarantine, and none during the present epidemic.

MEDICAL NOTES.

— A number of cases have been reported during the last few years of diseases having been communicated in consequence of that part of the rite of circumcision as practised by the Jews which has for its object the arrest of the hæmorrhage. So serious have those untoward accidents been judged that, as we learn from the *Medical Press and Circular*, the matter was recently brought before the Israelite Consistory at Paris. A committee of investigation was appointed, consisting exclusively of medical men, and after an inquiry extending over several months, they have reported in favor of a modification. As hitherto practiced, the religious rite of circumcision comprised three distinct operations, first the *Milah*, then the *Priah*, and lastly the act of suction, *Mezzizah*, for the purpose of preventing hæmorrhage. Notwithstanding energetic protests from the more conservative members of the Consistory, the abolition of the *Mezzizah* was decreed, and Dr. Duplay was requested to draw up, without delay, a new manual of directions for the guidance of heads of families in so far as this part of the rite is concerned. The change of custom is one which would seem to be a great gain, both to the operator and to the child, from the point of view of possible infection, to say nothing of the revolting character of the former custom.

— Dr. F. T. Pasternatski, according to the *Lancet*, in a lecture delivered before the professors of the Military Medico-Chirurgical Academy of St. Petersburg, for the purpose of showing his fitness for the position of *privat docent*, or extra-mural lecturer, in clinical medicine, brought together a number of statistics calculated to show the effect of different methods of treating typhoid fever upon the frequency of relapses. According to his figures, relapses occurred more frequently under cold-water treatment than when indifferent or inactive drugs only were employed. Still more frequently did relapses seem to occur when large doses of quinine — thirty grains per diem — were combined with the cold-water treatment. When large doses of antipyrin, thallin, and acetanilide were substituted for those of quinine, the results, as far as relapses are concerned, were even worse. There is, however, this to be said, that in Dr. Pasternatski's experience, none of the relapses proved fatal, or indeed left any permanent ill effects.

NEW YORK.

— The new wing of the Seaside Hospital of St. John's Guild at Cedar Grove, Staten Island, was recently opened with appropriate ceremonies. It measures 100 by 25 feet, and contains 64 beds; thus increasing the capacity of the Hospital one-half, so that it now accommodates 205 mothers and children.

Miscellany.

MACTE LISTER TRIUMPHATOR![1]

A MOIST-MERRY, HUMID-HILARIOUS ANTISEPTIC VADE-MECUM OF INTERNAL SURGERY, FOR THE AMBITIOUS MODERN PHYSICIAN.

BY DR. RISORIUS SANTORINI. Translated by "FAMULUS."

All Rights Reserved. 1888.

CHAPTER IV.

GASTRIC SURGERY.

Of all our organs there is none
So tolerant as the stomach, one
Which patiently accommodates
Much which our frame abominates.
We daily tax the best digestion
By most injurious refection.
But that the suffering stomach e'er
Resection should be called to bear,
And sutures multiple receive,
Surely nobody could believe!

[1] Concluded from page 214.

Loud praises let my song awaken!
Billroth this task has undertaken!
He first this operation planned
And took Hein's triumph from his hand.

. . . . . .

No herb has ever been secured
By which a cancer can be cured!
The therapeutist, helpless, waited —
He sometimes pain alleviated
By sedatives — but, after all,
The prognosis remained "lethal."

But numerous facts this truth reveal,
"What drugs can't cure, is cured by steel."
And this metallic necromancer
Soon gave a better fate to cancer.

It has been proved by Gussenbauer
That animals possess the power
To undergo normal resection
At the pyloric intersection.

Pean the same idea had cherished,
But all his patients quickly perished.
'T was in Vienna — city royal —
That, after years of effort loyal
In way of careful preparation,
A case was cured by operation.

But Kracer's classical review
States that, of cases seventy-two,
Details of which have been secured,
But seventeen are ranked as "cured."

Better results we hope to see
From gastro-enterotomie.
This was by Woelfler first invented,
And to our anxious view presented.
He sought the upper jejunum coil,
And sewed it to the gastric wall.
One thing seems like a serious poenam —
We must remove the duodenum
And the pylorus from their station,
Before we make the new relation.

In twenty-four reported cases,
Ten cures the careful list embraces.

We cannot promise full relief,
For oft there is a recidiv.
But in one case, six years, perhaps,
Have passed away without relapse.

With this in view, I see no reason
For failure, if it 's done in season;
But, first of all, the wise clinician
Must occupy the strong position
The case to diagnosticate,
And its attachments indicate.

But when we have the diagnosis,
And also learn by grave stenosis
The cancer sits at the pylorus,
Resection promptly comes before us;
But with cachexia evident
Naught can the fatal end prevent.

Even when there 's cicatricial stricture
A cure is not beyond conjecture;
But surgery, as all may see,
Now forms our only therapy.

But here we have much more to answer
Than when the malady is cancer;
For when the ulcer 's perforated,
Instant resection 's indicated.

'T is said that oft the inclination
Is to await the perforation
As *casus belli* in the case,
And then to operate apace.
Here, "indicatio vitalis"
Means also "exitus lethalis."

CHAPTER V.

ABDOMINAL SURGERY.

As in the chronicles recorded,
The ages past have oft afforded
Surgeons, alas, much underrated,
Who abdominal section cultivated,
With art and technical address,
And — *nota bene* — with success.

In Knidos, if the truth is stated,
The kidney first was extirpated.
In India we still earlier see
Records of laparatomy.

But in our present century
Our colleagues groped most helplessly.
Therapy reached its minimal
In lesions intra-abdominal,
From poultices in combination
With leeches and with sharp purgation.
You win but little comfort real
In lesions intra-peritoneal;
But ilius (or appendicitis)
Is deemed "lethal" in every treatise.

. . . . . .

Surgical Treatment of Peritonitis.

Active abdominal inflammation,
If it 's acute with suppuration
And cocco-bacterial infection,
You 'll treat, by Kroenlein's wise direction,
Hence as a surgical affection.

In any case the patient 's fated,
By doubt death 's but accelerated,
Excepting when the morbid action
Is checked by proper disinfection
And by intra-abdominal irrigation.

Yes — thus is cured — or environs —
Peritonitis perforans!!

I view with constant admiration
That case of iliac ulceration
Which (typhoid origin) perforated,
And peritonitis instigated,
As through the newly-formed hiatus
Parts of potato and tomatoes
Fell into the peritoneal space,—
And yet recovery took place.
Mikulicz's name is known afar
For surgical presbyopia.
He made abdominal division,
And did an ileum-excision;
With Lembert's sutures closed the bowel.—
Again the patient wields the trowel.

With antiseptic regulation
Cures often follow operation.

Another case — this is not bad:
Herr Kroenlein saw a country lad
With foul and purulent effusion
Who had indulged with great profusion,
In cherries, which, like Tommie Jones,
He swallowed, skin and pulp and stones.
These had produced a perforation;
But after nine long days' duration,
Kroenlein did laparotomy;—
The boy recovered perfectly.

Conclusio: In cases all
When in the abdomen we find gall,
Gangrene or putrid suppuration,
Urine, fæcal extravasation,
We trust to laparotomie; —
To puncture is bad surgery.

In empyæma of the belly
You must resort eventually
To surgery; but only then
You would incise the belly when
The place of bursting you can see.
Then boldly make an opening free.

(b) *Laparotomy in Ileus.*

Of all acute diseased conditions —
None know so well as our clinicians,—
There's none for man or medicus
So painful as is ileus.

With clysters and narcotica
We do not aid the sufferer.
Quicksilver, and the other lumber
Of useless drugs, which sometimes cumber
The doctor's brain, are still employed;
But no relief is thus secured.

Herr Kussmaul therefore advocates
Washing the stomach out, and states
That it succeeds; but I assure you
That this idea will but allure you
To disappointment. Dear colleague,
I would not try this on a pig.

Herr Roser proved statistically,
From death-reports in Germany,
Four thousand persons, more or less,
Die annually of ileus!!

He adds a fact quite pertinent
That a respectable per cent.,
Might be reserved to other fate
If boldly, and when not too late,
The doctor with incision free
Inspect the abdominal cavity.

. . . . . .

This is Internal Surgery:
If you employ it steadily,
'T will spread abroad your gory fame,
And all will tremble at your name!

. . . . . .

Behold our Science! I've outlined it,
If there's a moral you must find it.

FINIS.

IODOFORM IN HÆMOPTYSIS.

THE difficulty of finding any successful method of checking hæmoptysis in tuberculous cases has led to the trial of many remedies. MM. Chauvin and Jorissenne, of Liège, publish a short account of the results of the administration of iodoform, at first along with tannin, afterwards by itself. In the first six cases pills were given containing iodoform, $\frac{3}{4}$ gr., and tannin, $1\frac{1}{2}$ gr. Sometimes the hæmoptysis stopped after two of these had been taken; in one severe case of advanced phthisis, as many as five were given *per diem* for three days before the bleeding ceased. In another patient, who had been in the habit of having eight or ten attacks of hæmoptysis in the year, which had been treated by large amounts of ergotine and morphine, three of the iodoform and tannin pills stopped the hæmoptysis four months ago, and there has been no recurrence since. In the three cases recorded in detail, in which the iodoform alone was used, the results were very similar. The authors came to the conclusion that gr. ij. of iodoform *per diem* in three pills was an appropriate dose for moderately severe cases, and that more than eight or nine pills was not required in any case they had to deal with. This action they consider quicker than that of ergotine, and, therefore, more useful. In all the cases during the past year in which they had given it there has been no relapse, and, during the treatment, no disturbance of digestion. — *Progrès Méd.*, May 19, and *Practitioner*, July, 1888.

Correspondence.

ANTIPYRINE IN SEA-SICKNESS.

DENVER, August 27, 1888.

MR. EDITOR, — The following communication from so well-known a man as the sculptor-writer may be of interest to your readers as a contribution to the effects of antipyrine in averting sea-sickness: —

AT SEA, STR. TRAVE, 6 Aug., 1888.

DEAR DOCTOR, — I wish to send you a few lines to say that the antipyrine works wonders. I have never been to sea before without being more or less uncomfortable, the first day or two at least, even in as smooth a sea as we have had since we sailed from New York. This time, far from not enjoying every meal, I cannot get enough to eat. You can safely recommend it, for though *it* may not be the cause of my happiness, *something* is, and I am willing to give it the benefit of a doubt in the other direction. I only took it two days, — the day before sailing and the next. The ladies with me would none of them take antipyrine, and have all been more or less sick, - the youngest dreadfully so, and is no better.

Hoping you are well, and with kindest regards,

Yours truly,

PRESTON POWERS.

The above letter was written when six days out; and the dose of the drug was ten grains taken three times a day.

SAMUEL A. FISK, M. D.

"FREEDOM CURE FOR INSANITY."

BROOKLINE, September 3, 1888.

MR. EDITOR, — The *Boston Evening Transcript* of August 31st has an editorial headed "The Freedom Cure for Insanity," to which I wish to call attention, as it is unintentionally misleading.

As the text of the editorial was furnished by an article in the *Boston Morning Herald*, of the same date, on the "Boarding out of the Insane," which is a system of care for the *chronic* and practically *incurable* class, it will

readily be seen what a misnomer the title of the *Transcript* article is.

The object of this excellent experiment, which can hardly be called a substantial success until it has had a ten years' trial, is to help relieve hospitals of their surplus of old cases, which have passed the period of ordinary recovery. For this class, if carefully managed, it may to a certain extent be of use in connection with a general system of hospital provision for the insane.

However intelligent and worthy the wives of the lower class of farmers and mechanics may be, I doubt whether the *Transcript* writer would be willing to place an insane friend under their treatment, in spite of his high opinion of the "freedom cure" as he calls the boarding-out system. He would select rather the skilled medical treatment and thorough equipment of the insane hospital.

The words "freedom" and "liberty" are often wrongly applied when speaking of institution care of the insane. There are right and wrong uses of freedom, and the patient is often cured by taking away the opportunity for the wrong uses. Freedom in itself may be the worst thing possible for the patient.

Furthermore, patients in our best-managed lunatic hospitals have great freedom of action, if well enough to bear it, and often this freedom is greater than it would be at home.

No one believes more strongly in individual treatment of the insane than myself, and their treatment includes as much responsibility as the patient is equal to, but I often have reason to regret the hasty and superficial judgments expressed on this subject by persons who have had little practical experience in this direction. Writing as they do in the newspapers, they help to keep alive a spirit of distrust in lunatic hospital management, and retard the cause of hospital development.

WALTER CHANNING, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 25, 1888.

Deaths reported 3,180: under five years of age 1,541; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 1,002, consumption 311, acute lung diseases 141, diarrhœal diseases 624, typhoid fever 107, diphtheria and croup 104, whooping-cough 56, malarial fever 36, scarlet fever 31, cerebro-spinal meningitis 17, measles 13, puerperal fever nine, erysipelas three, small-pox two. From whooping-cough, New York 17, Brooklyn eight, Pittsburg six, Philadelphia, Chicago, and Washington each five, St. Louis three, New Orleans two, Boston, Cincinnati, New Haven, Somerville, and Brockton one each. From malarial fevers, St. Louis 13, Brooklyn seven, New York and Philadelphia four each, Charleston three, New Orleans two, Baltimore, Boston, and Cincinnati one each. From scarlet fever, New York 19, Brooklyn four, Philadelphia three, Cincinnati and Fall River two each, Chicago one. From cerebro-spinal meningitis, Chicago six, Worcester three, New York and Boston two each, Philadelphia, St. Louis, Cincinnati, and Washington one each. From measles, New York nine, Philadelphia, Brooklyn, Chicago, and Pittsburg one each. From puerperal fever, Chicago four, New York and Washington two each, Philadelphia one. From erysipelas, New York, Chicago, and Pittsburg one each. From small-pox, Philadelphia two.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273 for the week ending August 18th, the death-rate was 16.4. Deaths reported 2954: infants under one year 931; acute diseases of the respiratory organs (London) 167, diarrhœa 301, whooping-cough 56, measles 53, scarlet fever 31, diphtheria 23, fever 21, small-pox (Oldham) one.

The death-rates ranged from 12.9 in Bolton to 22.8 in Manchester: Birmingham 13.0; Bradford 14.5; Huddersfield 13.7; Hull 14.2; Leicester 16.0; Liverpool 18.1; London 16.2; Nottingham 12.9; Sheffield 20.6; Sunderland 13.4.

In Edinburgh 15.3; Glasgow 20.1; Dublin 18.2.

The meteorological record for the week ending August 25, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending Saturday, Aug. 25, 1888.	Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.		Velocity of Wind.		State of Weather.[1]		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. A., FROM AUGUST 25, 1888, TO AUGUST 31, 1888.

ALEXANDER, RICHARD H., lieutenant-colonel and surgeon. Detailed a member of Board to meet at San Carlos, A. T., August 28th, to select a site for a new post at that place. Paragraph 1, S. O. 44, Division of the Pacific, August 15, 1888.

ALDEN, CHARLES H., major and surgeon. Detailed as a member of the Board of Medical Officers convened at United States Military Academy, West Point, N. Y., *vice* Major Chas. R. Greenleaf, surgeon, relieved. Paragraph 2, S. O. 199, A. G. O., August 28, 1888.

CALDWELL, DANIEL G., major and surgeon. To report to the Recorder of the Retiring Board in session at Fort Leavenworth, Kansas, as a witness in the case of Capt. Thomas Sharp, 17th Infantry. Paragraph 2, S. O. 74, Department of the Platte, August 18, 1888.

CALDWELL, DANIEL G., major and surgeon. Having completed his duty as witness before Retiring Board, Fort Leavenworth, Kansas, to return to his station, Fort D. A. Russell, Wyo. Paragraph 4, S. O. 106, Department of the Missouri, August 24, 1888.

LORING, LEONARD Y., assistant surgeon. Granted leave of absence for one month. Paragraph 1, S. O. 97, Department of Arizona, August 23, 1888.

TAYLOR, MARCUS E., captain and assistant surgeon. Granted leave of absence for four months, to take effect about October 15, 1888. Paragraph 8, S. O. 196, A. G. O., August 24, 1888.

BIRMINGHAM, HENRY T., captain and assistant surgeon. Relieved from duty at Fort Myer, Va., and ordered to Fort Klamath, Oregon, for duty. Paragraph 18, S. O. 196, A. G. O., August 24, 1888.

BALL, R. R., assistant surgeon U. S. A., Fort Riley, Kansas. Ordered to Fort Servis, Colorado, for temporary duty. Paragraph 5, S. O. 108, Department of the Missouri, August 27, 1888.

SWIFT, EUGENE L., assistant surgeon. Upon being relieved from temporary duty at Fort Klamath, Oregon, to return to his proper station, Fort Spokane, W. T. Paragraph 18, S. O. 196, A. G. O., August 24, 1888.

RAFFERTY, OGDEN, assistant surgeon. To proceed from Fort Clark to the camp at the Department Rifle Range near San Antonia, Tex., and report for temporary duty. Paragraph 3, S. O. 85, Department of Texas, August 15, 1888.

RAFFERTY, OGDEN, assistant surgeon. Upon conclusion of Department Rifle competition, will report to the Inspector of Rifle Practice, Division of the Missouri, for assignment to duty in connection with the Division Rifle Competition as camp surgeon. Paragraph 4, S. O. 86, Department of Texas, August 17, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING SEPTEMBER 1, 1888.

CRANDALL, R. P., assistant surgeon. Detached from the "Saratoga" and wait orders.

DU BOSE, W. R., passed assistant surgeon. Detached from the "Jamestown" and to the "Constellation."

ARNOLD, W. F., Nashville, Tenn. Commissioned assistant surgeon in the Navy, August 18th.

LUNG, GEORGE A., Canandaigua, N. Y. Commissioned assistant surgeon in the Navy, August 18th.

SOCIETY NOTICE.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next meeting of the Society will be held at No. 19 Boylston Place, on Thursday, September 13th, at 4 o'clock, P. M. Paper: "Antiseptics in Gynæcological and Obstetric Operations," by Dr. F. L. Burt. Drs. E. W. Cushing and F. L. Burt will show interesting pathological specimens.

H. J. HARRIMAN, M.D., *Secretary*.

OBITUARY. GEORGE D. TOWNSHEND, M.D.

Dr. George D. Townshend, a prominent physician of Roxbury, died at Norfolk, Va., August 20th, in his forty-seventh year, after a protracted and painful illness which culminated somewhat suddenly. Dr. Townshend was born in Providence, R. I., and was a paternal great-grandson of General Glover, and a maternal grandson of General R. E. Lee. He graduated at the Medical and Surgical College in Philadelphia, where for six years he was lecturer and demonstrator of anatomy and surgery under Dr. Agnew. During the late war he was a surgeon in the Army of the Potomac. After the war he settled in Norfolk, Va., where he secured a large practice. The hostility of the South against Northerners engendered by the war, induced him to abandon this field, and in 1877 he removed to Massachusetts and settled in Roxbury, where his ability and industry gained him a good practice. He served for some years as Secretary of the Norfolk District Medical Society and later as its vice-president.

TWO CASES OF APPENDICITIS, ONE FATAL.

BY C. ELLERY STEDMAN, M.D., DORCHESTER.

A. B., AGED forty-one, a wool merchant, married, having two children, spare, abstemious, sandy complexion, travelled a good deal in the West on business; called himself a healthy man. But I attended him in 1882 for a prolonged attack of acute rheumatism, which left him much weakened, and from which he convalesced at Richfield Springs. In the past eleven years he has had several attacks of dysentery, and he suffered from constipation last winter. The testicle on the right side had never descended, and he always wore a truss, for what reason I never learned, as there were no symptoms of hernia. His parents were consumptive, and a sister died of phthisis.

On the morning of the 29th of March, 1888, he began to feel uncomfortable, and vomited in the afternoon: this he attributed to a richer breakfast than usual. The vomiting was followed by abdominal pain in the afternoon of no great severity: he felt a little chilly, but had nothing like a rigor. I was called early in the morning of the 30th, and found the patient suffering from the usual symptoms of colic. He was inclined to ascribe his distress to the missing testis, which he believed would "kill him some day." The little finger, however, passed into the inguinal canal easily, and far enough to eliminate the possibility of strangulated hernia. The pulse was but little quickened, and no fever was noticed. Towards afternoon, the pain, which had been quieted by a quarter of a grain of morphia, became more severe, and occupied the loins and right lower part of the abdomen, and the vomiting of bilious matter continued: the belly, which was naturally full, though tender on pressure, was little, if any, swollen; there had been no dejection.

31st. The temperature rose to 102°, and the pulse to 100: pain occurred as soon as the effect of morphia abated. Late in the afternoon the pain was intolerable, in the groin especially, shooting down into the penis: vomiting was distressing, and the countenance began to grow pinched: there was no escape of flatus nor any dejection. These conditions, with swelling and tympanites, were maintained till the 3d of April, the sixth day of the disease, when the suspicions of appendicitis grew stronger, and Dr. Fitz (who has kindly allowed me the use of his notes) was asked to see him.

The vomiting continued frequent, without offensive odor, both it and the abdominal pains causing sweating. Last night, a second attack of intense pain occurred, like that of yesterday. An enema discharged some scybala for the first time. The countenance was anxious, the pupils contracted, the skin not very hot, though he complains of flushes of heat. The abdomen considerably swollen and tympanitic, more marked in the right iliac fossa, where the outline of the cœcum is perceptible: slight dulness in that situation, but no tumor was recognized: the tenderness does not extend into the right loin. The severest pain is over the right inguinal canal, where there is a circumscribed resistance, and along Poupart's ligament, near the iliac spine: the right testis has never descended, and cannot be felt: there is sensitiveness on palpation in the left iliac region: the hypogastrium resonant, but not painful. On rectal examination, there is felt in the pelvis an elastic, rounded tumor, pressure on which causes pain locally and in the right iliac region. The urine passed freely during the day, the tumor persisting after micturition.

The gravity of the situation being explained to the family, Dr. Bolles was consulted with a view to immediate operation, and he saw the patient at once. But in the two hours which had passed there had been a remission in the symptoms: less pain, less swelling, a fall of temperature and pulse. The patient expressed himself so much relieved that the operation was not insisted on that night.

Next morning, the seventh of the disease, Drs. Fitz and Bolles saw him with me, and found him calling for something to eat. The vomiting had ceased at six o'clock that morning; the abdomen was less tense; there was no increased local tenderness; no tumor could be felt in the right iliac fossa. Pulse 104, temperature 99.4°. The operation postponed for more decided indications.

On the tenth day of the illness there was a slight chill at 3 o'clock, A. M., and the temperature shot up from 97° to 100°: loose dejections were passed; gruel, chicken-broth, tea, and toast allowed in sufficient amount.

12th. The temperature touched the normal figure in the evening: twenty-five drops of elixir of opium once or twice a day makes the pain bearable: abdominal distension less. Micturition frequent; urine normal in quantity.

16th. Induration detected in right iliac fossa; also a tumor discovered in the right inguinal canal, an inch below Poupart's ligament: it has the same size, shape, and density of the left testis, is not affected by coughing, is reddened, and is the source of much discomfort. The abdomen moderately distended; generally tympanitic; somewhat dull in right iliac fossa, specially so in right lumbar region; right rectus indurated, resisting deep palpation. Rectal examination shows the pelvic tumor still persistent, moderately tense, rounded. The temperature ranged, this week, from 99° and a fraction in the morning to a little more than 102° in the afternoon. He was taking one or two pints of champagne during the day; the pulse was 115 to 120, the face was pinched, and the patient evidently failing. The operation having become imperative, was done in the forenoon of the twenty-first day of the disease by Dr. John Homans.

After etherization, an incision was made just above Poupart's ligament, and carefully carried down to the peritoneum, which was torn off the iliacus muscle by the finger. The abscess was not readily reached, but by firm pressure on a point towards the left of the median line the finger was pushed through the peritoneum into a pus-cavity in the pelvis: out of this, on the withdrawal of the finger, spouted fully a pint of dirty, brown, highly offensive pus: following this, some yellow, flocculent fæces and gas.

The cavity was washed out with hot carbolized water, and a drainage-tube six inches long thrust down to the bottom of the wound. The rectal tumor disappeared with the evacuation of the matter. The temperature after the operation fell to 98.4°, and the pulse to 110.

In the afternoon, a chill sent the temperature to 102° and the pulse to 140, but he had a comfortable

night. The discharge of pus was very little, and milk nearly digested came through the tube, which was flushed every two or three hours with carbolized water. The range of temperature became irregular, dropping from 100.2° on the twenty-fifth day to 97°: the patient gradually failing, though he took milk and champagne in good amount. Thirty drops of tr. opii deodoratis would secure a good night.

Twenty-third day. At noon he complained of great pain in the left of the lower abdomen, which was repeated on following days.

Thirty-third day. The incised opening discharges freely fæces and gas. The borders of the wound show small sloughs: the rectal tumor no longer apparent. The nourishment is chiefly milk, and a quart of champagne is consumed daily. To-day is the first dejection per anum since the operation, and less discharge by the drainage-tube. Fæces appeared in the urine, with pain in micturition, and urine escaped by the wound, with little or none passing by the urethra.

Thirty-fourth day. The swelling in the scrotum broke to-day, discharging pus, and the tumor disappeared. After this he was tolerably comfortable, though weaker.

Thirty-fifth day. The opening into the scrotum was enlarged by incision by Dr. Homans. The next day he had a dejection per anum, and on the thirty-ninth day of his illness — the 6th of May — he died at 2.45 P. M.

The autopsy was made by Dr. Fitz. The abdomen only was examined. Coils of small intestine, the descending colon, sigmoid flexure, cœcum, and anterior abdominal wall united by fibrous adhesions easily torn. The pelvic portion of the peritoneal cavity was thus shut off, and held, perhaps, a half-pint of yellowish-gray, viscid pus. The cavity communicated freely with the incised wound in the right iliac fossa. The stump of the vermiform appendix, about half an inch long, opened directly into the upper part of the cavity. Its mucous membrane was thickened, reddened, and the surface rough. On the posterior wall of the bladder, about an inch and a half from the posterior border of the prostate, was a sharply-defined wound opening, quarter of an inch in diameter, through which the bladder and abscess-cavity freely communicated. The mucous membrane of the bladder was injected. The kidneys were normal. The right testicle was attached to the right abdominal wall at the brim of the pelvis: it was small and soft. On isolating the coils of small intestine forming the loop of the abscess, the walls were easily torn in several places. The mucous membrane of the lower part of the ilium and of the cœcum were normal. The peritoneal coat of the ilium showed numerous fibrous shreds and patches.

The second case was that of J. H., a large, fair man, thirty years old, foreman of the paint-shop in a large smithy. A year ago last fall he sustained a severe injury in one hand. He said that he was subject to constipation, which was relieved by beer, and he was thus induced to take a full allowance. He had had several attacks of colic, one or two of which I saw, the cause of which seemed to me to be gall-stones, having the symptoms of sudden pain just to the right of the epigastrium, and vomiting, yielding to opiates, so that on the third day he could go to work again. On the 15th of April (when my other patient had been ill eighteen days), Mr. H., who had been complaining for several days with dyspepsia and constipation, was taken in the night with acute abdominal pain, and sent to my house for an opiate.

On the 18th I was called to see him, and found that this time his pain was referred to the right and lower part of the abdomen: there had been no chill: he did not vomit till after he had several doses of opium. He preferred to lie with his knees drawn up: there was tenderness, not excessive, all over abdomen, but no tumor could be felt. Sleeplessness was his chief complaint, though he had had full opiates. The temperature was normal, and the pulse about 80. These conditions held for two days, and it was not till a fortnight afterwards that I learned that about the fifth day of his illness, being a little light-headed through opium, he dressed in ulster, trousers, and slippers, and crossed the street to his father's house, despite the efforts of his wife to restrain him. On the seventh day his temperature and pulse were increased, and, for the first time, a tumor, could be felt along and above the right groin, while, per rectum, the same could be detected and compressed by bimanual palpation. Dr. Fitz kindly saw him the next day in consultation, and procured his admission to the Massachusetts General Hospital.

Here, I understood, on the tenth day after his illness began, an operation was prepared for, but the preliminary examination showed a decided diminution in the size of the tumor, as compared with the day before; there was less pain and free defæcation, and the temperature gradually dropped to the normal standard. By the thirty-eighth day no tumor was to be felt in the iliac fossa on abdominal palpation, but a slight fulness could be detected on rectal examination. Discharged 24th of May.

The interest of these two cases to those chiefly concerned lay in the diagnosis and in the question of operation. Abundant information on these points in general is contained in the treatise of Dr. Fitz on this subject, published in 1886.

In a second paper (*N. Y. Medical Journal*, May 12, 1888), the same author sums up in these words: "It is the duty of every physician to be mindful that, for all practical purposes, typhlitis, perityphlitis, perityphlitic tumor, and perityphlitic abscess mean inflammation of the vermiform appendix; that the chief danger of this affection is perforation; that perforation, in the great majority of cases, produces a circumscribed, suppurative peritonitis, tending to become generalized; that, in the light of our present knowledge, the surgical treatment of this lesion offers the best chances for the life and the future health of the patient; and that the progress of the disease needs to be watched with knife in hand."

In the first case the situation was complicated by the undescended testis, and the diagnosis was settled on the fifth day, the determining symptom being the resistance and dulness felt about the right groin, following the renewal of intense pain, the tympanites, and the rise of temperature. An immediate operation was prepared for, and would have been done at once — in the night — had there not been an extraordinary remission of all the symptoms. The second case was not seen till the third day, as the patient supposed that the attack was one of biliary colic, like those he had been subject to. He afterwards recognized the difference in his sensations between this and former attacks of colic. It was not till the seventh day, two days after his excursion across the street, when I

thought him snug in bed, that fever came on, and I could feel the tumor above the groin and in the rectum, although I had, with the former case in my mind, been watchful of the symptoms. This patient also missed an early operation on account of a remission in the symptoms. Should his appendix ever see the light, it would be instructive to know whether it contained a gall-stone — for such a concretion has been infrequently discovered lurking in the appendix — and I consider that his earlier attacks were correctly diagnosticated.

Hospital experience early drew my attention to this class of cases, and I have seen a few in private practice, all of whom did well, the tumor in each being small and the symptoms not alarming. But I do not always find it easy to diagnosticate them as early as I should like, and I have found the tumor developed later than in cases described by others. But if the physician bears in mind that each patient who cries out with colic may be threatened with this disease, and if palpation of the abdomen is carefully employed in obscure or doubtful cases, he is not likely to be found often astray.

It is easy to be wise after the event, and to wish that the first patient had been operated on when the first preparations were made. But it was by no means easy to reach the abscess, large as it was, when laparotomy was done, and at an earlier time it might have been missed altogether, for I have heard that this operation has been abandoned from inability to find the source of disease. The marked improvement was no greater in A. B. than in J. H., who escaped laparotomy altogether after it had been postponed, as it was in A. B.'s case.

GELSEMIUM SEMPERVIRENS.[1]

BY G. M. GARLAND, M.D.,
Instructor in Clinical Medicine, Harvard Medical School.

The virtues of gelsemium have long been known to the eclectics, and many a celebrated eclectic febrifuge has owed its efficiency to this potent remedy. The gelsemium plant is a trailing woodbine which is familiarly known as Carolina jasmine or yellow jasmine from the color of its blossom. Flowering during March and April, it is a beautiful feature of the southern landscape as it hangs from the branches in festoons of bright yellow blossoms which fill the air with a fragrant perfume. Confined in a close room, however, the odor of these flowers is depressing, and causes headache. The root of the vine is the part endowed with medicinal properties; and the ordinary pharmaceutical preparations are a powder, an extract, and a tincture. It is well to say at the outset that gelsemium is an extremely powerful drug; and as its preparations vary widely in strength, it is wise for one to begin cautiously with those which are unfamiliar to him.

Potter describes the physiological action of the drug as follows: "Gelsemium is a powerful motor depressant, causing paralysis of motility and depression of sensibility by central action on the spinal cord. It is also antispasmodic and diaphoretic. In moderate doses it produces languor, slowing of the cardiac rate, enfeebled muscular action, impaired sensibility, drooped eyelids and dilated pupils, with some diaphoresis. In toxic doses, as a teaspoonful of the fluid extract, it produced vertigo, diplopia, drooped eyelids and dilated pupils, (paralysis of third nerve), labored respiration, slow and feeble heart, dropped jaw, staggering gait, extreme muscular weakness and almost complete anæsthesia, profuse diaphoresis, loss of articulation, and death of asphyxia from paralysis of the muscles of respiration, consciousness being preserved until CO_2 narcosis sets in. Convulsions occur in animals with backward movements, but not in man. Motion is affected before sensibility in warm-blooded animals, sensibility before motion in frogs. Gelsemium is not an arterial depressant, although it lowers the heart-rate, and is not irritant to the gastro-intestinal tract, but it produces a decided lowering of the body temperature. The effects of a moderate dose pass off in about three hours."

Phillips says it affects the sixth nerve before the third, as the external rectus is the first muscle weakened. Tweedy states that it impairs the power of accommodation of the eye for near objects, and one lady in my own practice complained after taking a moderate dose of gelsemium, that the dishes on the table appeared a long way off to her.

At the time I began to use gelsemium, eight years ago, there was very little said about it in our journals, and I was obliged to feel my way along with it. I began with the fluid extract and soon learned that it was a very powerful remedy, and I also learned that it is advisable to forewarn a patient of its peculiar action upon the eyes or it may create a family panic. I have been summoned several times to allay such panics where I have neglected this precaution.

I propose to specify in this article some conditions in which I have found gelsemium useful for mitigating suffering and correcting perverted nervous functions. Foremost among such conditions come *hysteria*. In those crises of cerebral excitement, which were formerly combatted by assafœtida and valerian, I know of no drug which can excel gelsemium. Inasmuch as it affects the motor regions of the nervous system before the sensory, it is usually necessary to push its administration until diplopia and heaviness of the lids appear, in order to reach satisfactory results. The following cases will illustrate its use:

A lady, subject to nervous attacks and severe neuralgia of one arm, was overcome by a visit of sympathy to some of the sufferers by the Bussey bridge disaster. She returned in a hysterical condition, talking excitedly about the suffering she had witnessed, weeping profusely, and holding on to her arm which pained her excessively. Her entire body was twitching and she could not control herself. Gelsemium, pushed to heaviness of the lids, enabled this woman to pass a comfortable night and resume her domestic duties on the next day.

A dressmaker called at my office at noon, complaining of great nervousness, sleeplessness of several days' standing, a feeling of a bunch in her throat and inability to eat or to attend longer to her business. I gave her a few drops of gelsemium, and ordered the dose repeated every hour until relief was obtained. She reported upon the following day that the second dose compelled her to close her eyes, and she slept several hours, awakening greatly refreshed and relieved of her distress.

Again, as a remedy for certain kinds of headache,

[1] Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, on the occasion of the annual meeting of the Massachusetts Medical Society, June 12, 1888.

gelsemium has no rival. Catarrhal headaches, and those which accompany dysmenorrhea and nervous debility from overwork, are amenable to gelsemium. This drug will also conquer neuralgias of the superior branch of the fifth pair when they are not referred from neighboring inflammatory or irritated conditions which should of course be sought out and treated if present. The headaches of Bright's disease may be mitigated by gelsemium, but I have had no success with it in ordinary bilious or sick-headaches.

CASE I. Catherine Driscoll entered Carney Hospital with the history of constant pain in the upper part of her head for five weeks. She had tried various remedies without relief, and finally she had resorted to morphine, which was required in large quantity to stop her pain. Upon the first day in the hospital she was given guarana and bromides, but without producing any impression. At the next morning visit she was ordered one pill of atropine containing one sixtieth of a grain and five drops of the fluid extract of gelsemium, repeated every twenty minutes until she had received twenty drops. The pain almost entirely left her before night. A similar dosage was repeated on the following day, and the cure was complete in four days. Her general condition began to improve immediately. I will add that the morphine was stopped entirely at the beginning of this treatment.

CASE II. Joseph O'Neil entered the hospital for severe frontal pain of several weeks' standing. As there were specific antecedents in his history, he was given Shaw's mixture for a few days, but without effect. Then he was ordered three drops of gelsemium every twenty minutes until twenty drops were taken. This treatment produced immediate relief from the severity of his pain, but was continued twenty-two days before the cure was complete.

CASE III. Patrick Foley, forty-two years of age, appeared at the Boston Dispensary with a headache of six days' standing. "Regular racking pain in the forehead." Begins at 9 A. M., and lasts all day. Does not ache at night. Sleeps well. Appetite is good. Bowels very regular. Has no idea what started his headache. Came on while he was at work as longshoreman. He has a slight headcold, but he has that often. Pulse 72. Forehead is covered with blisters from the strong ammonia which he has applied. He was ordered one pill only of atropia, one-hundredth of a grain, and three doses of the fluid extract of gelsemium every half hour until physiological effects are produced or relief obtained.

Upon the following day he reported great improvement. He took three drops every half-hour until he had taken forty-five drops, and then felt as if he were intoxicated. "Dizzy and flimsy like," but not sleepy. The light looked hazy about him. He felt slight headache on awaking in the morning, and took three drops more, which affected him immediately. He has a slight pain now, but yesterday morning it was so great that his hat seemed lifting off from his head.

This was evidently a headache associated with a slight head-cold. It is noticeable that one dose on the second day produced symptoms which required forty-five drops on the previous day. Pain seems to be an antidote to gelsemium as it is to morphine, and physiological effects appear more readily after the pain has abated. The next case also illustrates this point.

CASE IV. J. A. M., merchant. Appeared at my office on a Friday. He had contracted a head-cold on the previous Monday, and this quickly developed a severe frontal neuralgia, which was constant during the day, although it did not prevent sleep at night. His nose was stopped up, his eyes were swollen and ached badly. I gave him a mixture containing two drachms of the fluid extract of gelsemium in four ounces of water, and told him to take a spoonful every two hours. His headache ceased that afternoon. Next day he took one dose upon rising and one more about ten o'clock, when he found that he could not see, and he staggered against people. A friend thought he was intoxicated. Four hours' sleep restored him to equilibrium and he had no more trouble from his headache or his cold.

In the early stage of acute bronchitis when the cough is disturbing, tubes are dry, and there is pain across the chest, gelsemium will relieve this distress, start up the bronchial secretions, thereby furnishing material for expectoration and diminution of the inflammatory tension. The bronchial glands are not the only ones influenced by gelsemium. The sweat glands are also subject to its action, and, given under proper conditions, this drug is an unfailing diaphoretic. Follicular tonsillitis is usually accompanied by soreness of the throat, high fever, neuralgic pains in the head, back and legs, all of which discomforts abate rapidly with the diaphoresis induced by gelsemium. In such cases I cover the patient with plenty of blankets, order him to keep his arms and hands under the clothing, and give him three to five drops of gelsemium every hour until he sweats or has taken fifteen to twenty drops.

The relief to the suffering is rapid, and the patient usually sleeps while he sweats. Acute muscular rheumatism is also amenable to this kind of sweat. Gelsemium will allay excitable reflexes, and diminish the nervousness of passive cerebral congestion, and some writers claim good results from its use in acute meningitis.

Dr. McKay, of St. Louis, recommends gelsemium to replace quinine for malarial chills. He gives one-quarter to one-half drop doses of the fluid extract every twenty minutes, beginning three hours before the expected chill, and he has had excellent results from this treatment. Dr. Charles G. Davis, of Chicago, gives small doses of gelsemium to soften a rigid unyielding os, and he says that fractional drop doses at frequent intervals will diminish after-pains. Dr. M. L. Chamberlain, of Boston, combines gelsemium with quinine to correct the ringing in the ears and headache, which the latter drug often cures. By means of this combination he has been able to give quinine to sensitive patients, who were otherwise unable to take it.

The dose of gelsemium depends upon the preparation used and the results which one desires to obtain. For the relief of neuralgias one should give three to five drops every half-hour or every hour, according to the intensity of the pain. To produce sweating, one drop every half-hour is sufficient, but the patient should, of course, be well covered up in bed, and protected from the cooling effects of surface evaporation. One drop of the fluid extract every hour will relieve the cough and discomfort of acute bronchitis, and fractional drops can be used as above cited. The tincture of gelsemium is slightly weaker than the fluid extract. The active principle in gelsemium is gelsemin, which can be given in one-quarter to one-half grain doses, but I pre-

fer the plain drug itself. For convenience the extract and tincture can be prepared in tablet form of one minim each, and then dissolved for fractional doses.

In regard to antidotes for gelsemium, Potter says: "Morphine is the most complete antagonist, so are also digitalis, ammonia, alcohol, and to some extent the tincture of xanthoxylum fraxineum. Emetics, heat, faradization of the respiratory muscles and artificial respiration are measures of prime importance. The cardiac alkalies and tannic acid are chemically incompatible."

The advantages which gelsemium can legitimately claim are:

1. It has an agreeable taste, and is not repulsive to adult or child.

2. It does not irritate the stomach or bowels.

3. It produces no depressing after-effects from ordinary doses. The sleep is natural and the patient awakens refreshed.

4. In ordinary doses it causes no depression of the heart, and it can be used in all forms of organic disease of the heart.

5. It does not create a habit. There is no depression of nerve centres following its use, and therefore no craving for more of it.

6. Its toxic symptoms are very characteristic and striking, and they appear early, so that plenty of warning is given.

DEMONSTRATION OF A MODEL OF FROZEN SECTIONS OF THE ARM, WITH REMARKS ON THIS METHOD OF TEACHING ANATOMY.[1]

BY THOMAS DWIGHT, M.D.,
Parkman Professor of Anatomy at the Harvard Medical School.

I have the honor of showing the Society to-night the plaster model of the arm of twice the natural size by linear measurement. It is cut into a series of slices, seventeen in number. This is a very accurate model of an arm made into frozen sections during the past winter at the Harvard Medical School. It lies in the stand with the outer side of the shoulder looking upward, and the forearm is moderate pronation. The surfaces of the slices are painted from the actual specimen. As I believe I may claim to have introduced the study of frozen sections into American schools, I would take this opportunity of saying a few words on their value as means of learning and teaching anatomy, and of the proper method of using them.

The first feeling in attempting to understand a frozen section is one of bewilderment. Hyrtl called them anatomical puzzles. It is not till one has acquired a certain familiarity with them that they become intelligible. This familiarity comes much more quickly if the sections admit of being put together so that the student may both see where the line of section falls and also imagine the position under the surface of the body of the various structures which he sees cut through. One of the great advantages of a model of this kind is that when a slice is taken out to be shown the others remain in place, and the student sees precisely where it comes from. It is evident, also, that for the lecture-room the actual sections, with the exception, perhaps, of those of the trunk, are too small, hence the advantage of enlarged models, or, failing these, enlarged diagrams.

[1] Presented before the Section for Clinical Medicine, Pathology and Hygiene of Suffolk District Society, on the occasion of the annual meeting of the Massachusetts Medical Society, June 12, 1888.

Allow me now to show this model in some slight detail. We recognize here on the surface the projection formed by the head of the humerus, and the faint outline of the acromion and clavicle. This section shows us the large head of the humerus, the detoid covering it, the deeper muscles passing to the tuberosities, the long head of the biceps in the groove. Lower down we see the narrow neck, the circumflex nerve and vessels curling round it, so that we can see from which side the joint may be best opened for a resection without injury to this important nerve. The piece being replaced, we see the groove along the outer edge of the biceps, in which runs the cephalic vein. The inner groove, the guide to the artery, is hidden as the arm lies. We, therefore, on taking out a slice, find the artery at the lower side. By examining a series we follow the course of the musculo-spiral nerve twisting round the humerus. Lower down we see the olecranon and the outer condyle, and can easily imagine the point a little below and behind the latter where we should feel for the head of the radius. We verify all these points on the sections which are here very striking, owing to the great changes of form which rapidly succeed one another. We see the ulnar nerve in the hollow between the olecranon and inner condyle. The bifurcation of the brachial is somewhere in the thickness of one of the slices. In the same way we can study the changes of size, shape, and relative position in the bones of the forearm. The transformation of muscles into tendons, the arrangement of the latter at the wrist, the complication of the bones of the carpus, and the simplicity of the succeeding metacarpus are shown on the following slices.

Two criticisms were made some years ago by Professor Ranney, of New York, on the value of frozen sections. The first one was that you never find two alike. This, to my mind, is a very puerile objection. Indeed, it is rather to be regarded as a compliment, for it shows that the sections tell the truth. What two bodies are perfectly alike? And if the surface differs the section must necessarily differ also. Further, as is well known, both to anatomists and clinicians, the position of the internal organs is by no means always the same, and this is never shown so strikingly as by frozen sections. The second criticism, on the other hand, is a very weighty one. It is that frozen sections show structures as they are in the dead, and not as they are in the living body. Apart from the influence of cadaveric changes, the element of muscular tonicity is usually wanting, and this has its effect on the soft parts. Perhaps it has already occurred to some of my hearers that this model is very evidently one of a dead arm. Such it undoubtedly is. My reason for having it made thus was that I wished the sections to be drawn from the actual specimens, and I preferred copying a dead arm accurately to having the handsomer model of a living arm, and painting the sections by guesswork to make them correspond. I am far from considering that this drawback detracts seriously from the value of frozen sections, but the fact must be borne in mind.

In frozen sections through the pelvis the anus is almost invariably patulous. In the museum there is a median section of the pelvis made by Dr. L. J. Mixter, in which the walls are in apposition for about an inch where the sphincter ani surrounds it. I presume the subject must have been at least slightly frozen soon after death, during the rigor mortis, before the sphinc-

ter became relaxed. I can see no reason to doubt that under these circumstances the relations are those of life.

I have used frozen sections for years in teaching anatomy, and expect to use them more year by year. The Warren Museum of the Harvard Medical School contains probably by far the finest collection in the country. I hope members of the Society will not fail to visit the museum, and will especially notice a section made by Dr. O. K. Newell from the crown of the head through the pelvis. There is now making a model of the leg on the same scale as this one of the arm.

Before closing, I would say a word on the use of the living model in conjunction with frozen sections. There is nothing original certainly in the use of the living model. I remember when I was a student Dr. Bigelow occasionally introduced one. Dr. Holmes showed the "living skeleton" to the class, and other gentlemen have occasionally used models.[2] I have found, however, that the model deserves a regular place among the methods of anatomical teaching, and have used him regularly for years, but I recently have adopted the plan of using the live model in conjunction with frozen sections, and I believe that much is to be gained by the combination, as one method assists the other.

REPORT ON PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

TREATMENT OF HERNIA CEREBRI.

MACLAREN [1] reports a case where a man on the third day after a fracture of the skull had the depressed fragments elevated and the loose fragments of skull removed. A hernia cerebri was first cut off on the ninth day. On the forty-second day the hernia cerebri was removed for the third time, and a silver plate was firmly secured inside the skull. The plate was a florin rolled out to about four times its original size. It was then cut down to fit the opening in the skull, and was made self-retaining by nicking its edges. It did not fit exactly, which Maclaren considered an advantage, as it allowed drainage. So long as the plate was in position no hernia cerebri occurred, and there was singularly little irritation. The plate was removed on the one hundred and fourth day, the edges of the scalp pared and brought together.

BONY ANKYLOSIS OF THE TEMPERO-MAXILLARY JOINT AND ITS TREATMENT.

G. Zipfel [2] has made a careful study of five cases treated by osteotomy and twenty-one cases treated by resection. Osteotomy he speaks of as performed in the following different ways: (1) It may be linear, through the condyles of the maxilla; (2) cuneiform invoving the neck of the condyle; (3) linear, through the coronoid process; (4) linear, through the neck of the condyle and the coronoid process together. Zipfel considers that resection is preferable and proposes the following operation:

1. An incision is to be made four cm. long, starting from the supra-glenoid root of the zygomatic arch running downwards and slightly forwards, and not extending deeper than the subcutaneous cellular tissue for fear of wounding the tempero-facial nerve, which the author finds crosses over just an inch below the arch; if the coronoid process has to be dealt with, an extra incision of three cm. has to be made running in the direction of the zygoma, and, therefore, harmless.

2. Recognize and push aside the lobules of the parotid gland. Keep the nerve-trunks out of the way by means of a blunt hook; the condyle and its neck can then be easily got at.

3. The periosteum has to be scraped off the bone, care being taken not to wound the maxillary artery.

4. A curved sound with a groove is passed beneath the condyle and along it is slid a chain saw. In operating, the buccal cavity is not opened.

[2] Gazette Médicale de Paris, July 2, 1887.

[2] To Dr. Keen, of Philadelphia, belongs the credit of having done the most to make this method of instruction popular in America.

THE PROGNOSIS OF EXTIRPATING THE LARYNX.

Maydl [3] states that in one of his cases which had been free from recurrence for twenty-five months, this afterward occurred, and he, therefore, believes that a case cannot be considered to be definitely cured until three years after operation, merely because recurrence has not been observed within this time. Of sixty-five cases operated on thirty died in a short time after operation, twenty died within nine months after operation from recurrence. Eight cases were at this time without recurrence, but in only two cases could it be said that a definite cure had been effected (thirty-four months and four years after operation.)

Sir Morel Mackenzie [4] has collected one hundred and three cases of extirpation of the larynx for carcinoma, and six for other causes, a total of one hundred and seventeen. Of these twelve, or about ten per cent., lived twelve months after the operation.

ACUTE THYROIDITIS.

Dr. Barlow [5] read a paper on "Acute Enlargement of the Thyroid Gland," at a recent meeting of the Clinical Society, and he related the case of a little boy, aged three, in whose thyroid gland an attack of inflammation occurred, which lasted altogether about a fortnight. The child had just previously suffered from erythema nodosum on the legs, and it was whilst recovering from this affection, and after having been out in the park, that the thyroid enlargement commenced in association with a nasal catarrh, of which the chief symptom was a discharge of thin glairy mucus. Reviewing the literature of the subject, Dr. Barlow arrived at the conclusion that his case must be regarded as coming under the "idiopathic" class of Lucæ, and although there had been erythema and nodosum, still the absence of arthritis and heart disease or other genuine rheumatic manifestations formed a warranty for not considering the case as of true rheumatic nature. Some observers, chiefly abroad, have noted a rheumatic swelling of the thyroid having a definite relationship with well-founded rheumatism: and Dr. Angel Money quoted a case of this character from his own experience. Mr. James Berry narrated many interesting particulars concerning acute enlargement of the thyroid gland; and some of these having a fatal ending might tally with cases like the one narrated by Dr. Barlow, in which the enlargement at one time had a threatening aspect. Nevertheless, the definite cycle run by cases of rheumatic and idiopathic descriptions must, we think, be held to differentiate them from or-

[3] Jour. of Laryngology, April, 1887.
[4] Jour. of Laryngology, Dec., 1887.
[5] Med. News.

dinary goitre, in which the mode of commencement may be acute, but the course always chronic, and showing recurrent tendencies. The perusal of Dr. Barlow's paper will raise the reflection that the causation of acute thyroid enlargement is as imperfectly known as it is seemingly various.

THE TREATMENT OF CAROTID HÆMORRHAGE.

In four cases Treves [6] has successfully treated severe carotid hæmorrhage, by the following method:

In the neck, pressure upon the carotid artery cannot be applied with success, or maintained for a serviceable length of time. The vessel can, however, be very readily occluded for a while and the carotid circulation arrested without the artery being permanently closed. This is effected by exposing the artery in the usual way and passing around it a thick piece of soft catgut. This is tied in a very loose loop. By pulling upon the loop the circulation through the vessel is at once arrested, but is, however, at once restored when the tension upon the loop is relaxed. Without discussing the possible value of this procedure, the following case may be briefly detailed.

A man, aged twenty-five, was brought to the London Hospital in 1880, bleeding profusely from a deep wound in the neck, about the level of the great cornu of the hyoid bone. While attempting to open a soda-water bottle the bottle burst, and a fragment of glass was driven into the neck. The cut made was less than one inch in length. The glass had been removed. The bleeding had been very profuse, and was arterial. The patient was blanched and almost insensible. The radial pulse could scarcely be felt. The bleeding was for the time checked by pressing a tampon against the wound. It was obviously useless to attempt to find the bleeding point while blood was welling up from so deep a wound. I, therefore, at once exposed the common carotid artery through a lower incision and placed a catgut loop around it. Traction upon this arrested all bleeding. The patient was placed in bed and surrounded with warm bottles. His condition was so grave that I did not feel disposed to search for the bleeding point. Traction upon the loop was maintained for half an hour. On relaxing the catgut no bleeding took place, and it never again recurred. The loop was left *in situ* for four days, when it was removed. The man, who was in vigorous health at the time of the accident, made a rapid and uninterrupted recovery. I supposed the bleeding to have come from the superior thyroid artery.

ŒSOPHAGOTOMY.

Fischer's analysis of seventy-nine cases of this operation on account of foreign bodies [7] yields the following information: Number of cases, 80; 62 successful, 16 fatal; shortest interval between accident and operation, one-half hour, and longest twelve years. The foreign bodies in a majority of cases were bones or artificial teeth accidentally swallowed while eating. Fischer regards the operation as one of relatively little danger. Fistulæ never result, and strictures, subsequent hoarseness, or severe cough, are quite rare. Death in the fatal cases is most often due to ulceration of the mucous membrane, and perforation, mediastinal abscess, pleurisy, pneumonia and pulmonary gangrene. In other causes exhaustion, probably the result of fasting due to painful deglutition preventing ingestion of food. In the fatal cases it is considered that death was probably the result of delayed surgical treatment rather than from the operation. A gentle attempt should be made to force soft food or smooth hard bodies into the stomach with a gum-elastic œsophageal bougie. Large pointed angular bodies which are liable to wound the wall of the alimentary canal are to be removed per orem with an umbrella probang; the same is true of long angular bodies. Small hard bones not especially sharp or angular are preferably removed through the mouth, but may be also displaced downwards. If the body cannot be dislodged, œsophagotomy should be performed, in connection with which the following facts are important. Inflammatory infiltration, cervical and peri-œsophageal, may occur two or three days after the body is swallowed, and ulceration, gangrene and perforation of the œsophagus on the fourth day. An impaction may, after a few days, cause swelling of the thyroid, by which an operation is made more difficult. Fasting from impeded deglutition rapidly weakens a patient, who, after a week, may reach a state of extreme exhaustion. The mortality is twelve per cent. less when performed within two days than when it is delayed to the third or fifth day, and Fischer has, therefore, concluded that an operation should be done at the end of forty-eight hours if bloodless manipulation is unsuccessful. If an attempt has been made to remove the body on the first day, the surgeon should wait twenty-four hours before making a second attempt, which should be the final one before operating. If a foreign body has been already impacted several days before an attempt has been made to dislodge it, bloodless methods should be at once followed by œsophagotomy. The surgeon should operate at once when the character of the impacted body renders an attempt to move it dangerous; for example an open clasp-knife. Tracheotomy should be at once performed when the foreign body is in the trachea. When a clean wound is made into a healthy œsophagus through uninfiltrated tissues it is desirable to close the œsophageal wound at once by suture, and drain the external wound under an antiseptic dressing. Perforation, gangrene or inflammatory infiltration of the surrounding soft parts contraindicate such treatment, and the wound should be treated unclosed. The use of an œsophageal tube for feeding is discouraged, for whether the œsophageal wound remains closed or open the patient can generally swallow small amounts a few hours after the operation.

THE TREATMENT OF AORTIC ANEURISM BY THE INTRODUCTION OF STEEL WIRE.

White and Gould [8] treated an aortic aneurism by introduction of thirty-two feet of steel wire; (Moore's method) the case ended fatally. They make the following deductions from the sixteen cases that have been treated by Moore's method: (1) Moore's treatment is worthy of careful trial in properly chosen cases; (2) the operation should be performed before there is reason to suspect rupture of the sac; (3) only a small quantity of wire should be introduced at any one time; (4) No firm pressure should be made over the aneurism afterwards.

A MODE OF FIXATION OF THE SCAPULA.

Mr. W. Arbuthnot Lane has a number of times

[6] Lancet, Jan. 21, 1888. Med. News.
[7] Deutsche Zeit. f. Chir., XXV, p. Hft. 6.
[8] Med. Chir. Trans., Vol. LXX, p. 277.

placed the profession under obligations to him in the elucidation of various obscure facts. Notably in regard to the mechanism and frequency of fractures of the first rib. Mr. Lane has carefully studied the relations existing between the coracoid process and the clavicle, when the arm is in an extreme degree of flexion.[9] He finds that when the arm is fully extended that the upper surface of the coracoid process is in contact with the under surface of the clavicle, and that frequently in a certain number of burden bearers that there is an eburnation of the bones at the point of impingement, and further that when the bones are in this position to one another that the scapula is practically fixed. The practical application of this fact is that, when a surgeon is obliged to break up adhesions in a joint, that this is the position the humerus should be placed in, and he states that when the humerus is in this position that the scapula is fixed and that the motions of rotation, complete adduction, and abduction may be performed.

A NEW METHOD OF REDUCTION OF DISLOCATIONS OF THE SHOULDER.

Abril [10] brings forward the following method for the reduction of dislocations of the shoulder.

In all the methods ordinarily employed for the reduction of dislocations downward of the humerus, the trunk is fixed and the head of the humerus is raised into the glenoid cavity. Dr. Abril inverts this proceeding; his plan is to fix the humerus and to make the glenoid cavity descend on to the head of the humerus. He claims for his method that it is most simple, easily and quickly done, that chloroform is not necessary to obtain muscular relaxation, that the pain is trifling, and that no assistants are required. He makes the patient stand with a crutch in his axilla; he then holds the hand of the affected side, making slight traction downward; the patient is now to let himself down as if he were going to fall on his knees, and as he falls the head of the humerus glides into its normal position, and the patient is surprised at finding himself cured.

AN ANALYSIS OF TWO HUNDRED AND SEVEN CASES OF MAMMARY CARCINOMA.

Gross [11] find that 82.47% were carcinomatous.

6	first	appeared	between	20	and	29	years	of age.
39	"	"	"	30	"	39	"	"
78	"	"	"	40	"	49	"	"

1	"	"	"	70	"	79	"	"

Children had been borne by 86.36%, and rather more than 90% of these had nursed their children. The patients' general health was excellent in 69.56%, indifferent in 17.39 %, and bad in only 13.04%. The disease was ascribed to traumatism in 9.66%, but the tumor developed within six months in less than half of these. In only two of those that nursed was it clear that the tumor had started from the induration. In 2.41% there was antecedent non-puerperal mastitis, and in four-fifths of these the disease started at the seat of crusts and scabs for several years before the appearance of the tumor. In 2.9% it began as Paget's disease of the nipples, or as a malignant papillary dermitis. In 4.83 per cent. it was inherited in direct line of descent.

The seat of election was the upper and outer portions of the gland and the immediate vicinity of the areola and nipple. In 80% of the cases pain of a sharp intermittent character was experienced; in about 15% there was merely a sense of discomfort, while in about 5% there was no discomfort whatever. The skin was involved in 74.87%, being met as early as two weeks and as late as twenty-nine months, averaging 12.6 months.

The opposite breast was infected in 3.86%, appearing on the average at 21.5 months. Infection of the axillary lymphatic glands was detected in 65.70%; the supra-clavicular in 7.20%; the sub-clavicular in 1.40%, and the cervical 1%.

This percentage is susceptible of increase, however, since in latter operations, where the axilla has been invariably cleaned out, these glands were affected in 95.35%.

Of the first 100 cases, 91.75 were marked by local reproduction, and he was unable to find a single recovery. In these cases the axilla was not cleared out. In the second series, 107 cases, he speaks with certainty of 53 cases, of which ten died without operation. Local reproduction occurred in 52.77% of the operations in the average in seven months.

The average life of the thirteen who died with recurrence was thirty-two months, varying from two to ninety-four months. The average period since the operation upon those who still survived without recurrence was three years and three months, varying from eight years and three months to six months.

A NEW METHOD OF FORMING A SPHINCTER AFTER GASTROSTOMY.

The following ingenious method is described by Girard [12] to avoid the leakage from the gastric opening which almost invariably occurs. Through a vertical incision (about fifteen centimetres long) the left rectus abdominis muscle is divided in the upper portion and in the median line. The peritoneal cavity is opened near the middle of the cut, and a wedge-shaped portion of the stomach near the fundus drawn out through the wound. A row of silk sutures which penetrate the post sheath of the rectus, the edge of the peritoneal wound and the stomach wall at the base of this protruding portion fix the stomach in the wound. An incision about ten cm. long and parallel to the operation wound is now made on either side of the latter, so that two strands of muscle fibre about the thickness of a finger are formed. These bands are now crossed laterally, and the stomach drawn out through the sphincter-like opening. The muscular bands and the gastric pouch are now fastened in place by sutures, after which the stomach is opened. Girard hopes in this way to obtain a sphincter controlled by muscular contraction, or by the tension of the rectus on the cicatrix should atrophy of muscular fibre result. The early death of Girard's patient from exhaustion not the result of the operation, prevents its inventor from making any statements in regard to its efficiency in guarding the opening of a gastric fistula.

RECTAL INSUFFLATION OF HYDROGEN GAS AS AN INFALLIBLE TEST IN THE DIAGNOSIS OF VISCERAL INJURY OF THE GASTRO-INTESTINAL CANAL IN PENETRATING WOUNDS OF THE ABDOMEN WITHOUT LAPAROTOMY.

This method, which was brought forward by N.

[9] B. M. J., May 19, 1888, p. 1047.
[10] Lond. Med. Rec., Dec. 15, 1887.
[11] Med. News, Nov. 26, 1887, Ann. Surg., June, 1888, p. 454.
[12] Wien. Med. Presse, 1888, No. 25, Bd. XXIX, 926.

Senn at the American Medical Association,[13] has already demonstrated its usefulness in two recorded cases; in Mackie's case [14] it certainly freed the surgeon from a large medico-legal question, in that it settled the diagnosis of a visceral injury in an assault with intent to kill. In the second case by Keen, and reported by Taylor, it was used to determine the seat, whether in the large or small intestine of a fæcal fistula;[15] this it accomplished.

Below are given Senn's conclusions:

1. The entire alimentary canal is permeable to rectal insufflation of air or gas.

2. Inflation of the entire alimentary canal from above downward, through a stomach tube, rarely succeeds, and should, therefore, be resorted to only in demonstrating the presence of a perforation or wound of the stomach, and for locating other lesions in the organ or its immediate vicinity.

3. The ileo-cæcal valve is rendered incompetent and permeable by rectal insufflation of air or gas under a pressure varying from one-fourth of a pound to two pounds.

4. Air or gas can be forced through the whole alimentary canal, from anus to mouth, under a pressure varying from one-third of a pound to two and a half pounds.

5. Rectal insufflation of air or gas, to be both safe and effective, must be done *very slowly and continuously.*

6. The safest and most effective rectal insufflator is a rubber balloon large enough to hold four gallons of air or gas.

7. Hydrogen gas should be preferred to atmospheric air or other gas for purposes of inflation in all cases where the procedure is indicated.

8. The resisting power of the intestinal wall is nearly the same throughout the entire length of the canal, and in a normal condition yields to a diastaltic force of from eight to twelve pounds. When rupture takes place, it either occurs as a longitudinal laceration of the peritoneum on the visceral surface of the bowel, or as multiple ruptures from within outward at the mesenteric attachment.

9. Hydrogen gas is devoid of toxic properties, non-irritating when brought in contact with living tissues, and is rapidly absorbed from the connective-tissue spaces and all of the large serous cavities.

10. The escape of air or gas through the ileo-cæcal valve from below upward is always attended by a blowing or gurgling sound heard most distinctly over the ileo-cæcal region, and by a sudden diminution of pressure.

11. The incompetency of the ileo-cæcal valve is caused by a lateral and longitudinal distension of the cæcum, which mechanically separates the margins of the valves.

12. In gunshot or punctured wounds of the gastro-intestinal canal, insufflation of hydrogen gas enables the surgeon to determine positively the existence of a visceral injury without the risks and medico-legal responsibilities incident to exploratory laparotomy.

CONTUSION OF THE ABDOMEN WITH RUPTURE OF THE INTESTINES.

B. Farquhar Curtis [16] arrives at the following conclusions on this subject:

"(1) The treatment of contusion of the abdomen should be purely expectant in the early stage, until symptoms of internal injury have appeared, or until the full extent of time in which they may be expected has passed. Exploratory laparotomy at this time is inadmissible. (2) When symptoms of uncontrollable internal hæmorrhage or serious visceral injury appear laparotomy is indicated; but when the diagnosis is uncertain the operation should always be begun as an exploration. (3) Great collapse is an absolute contraindication to all operative interference. (4) When rupture of the intestine is found, the best method of treatment is to secure the injured gut in the abdominal wound, and form an artificial anus. This can be easily relieved by a later operation when the patient has recovered his strength."

LAPAROTOMY FOR ACUTE INTESTINAL OBSTRUCTION.

An admirable analysis of all the reported cases since 1873, when the principles of antiseptics may be said to have first come into general use, is made by B. Farquhar Curtis.[17]

Table I shows a total of 328 cases, with 102 recoveries and 226 deaths, the percentage of mortality being 68.9%.

Table II shows clearly that the percentage of mortality is increased by delay. There are a number of other tables which give us various phases of the question.

The rival to laparotomy in acute intestinal obstruction is enterostomy, and the statistics of Treves give a mortality of 41 out of 61 cases, 67.2%. This is not much better than that for laparotomy, 68.4%.

"When the operative interference was limited to finding and removing the obstruction, without wounding the bowel, the mortality was only 56.4%, calculated on 186 cases; when it was necessary to establish an artificial anus after the obstruction had been relieved (owing to gangrene or rupture of the gut) the mortality rose to 66.6% in fifteen cases; and, finally, when an attempt was made to suture the wound in the intestine, whether it involved the entire circumference or not, the mortality reached the extreme point of 86.6% in 45 cases. Only 10% of the deaths in the last two classes of cases were from sepsis due to the operation, and not more than the usual number, 50%, were due to the condition of the patient, while 23% were due to the operation and to shock."

Finally, the author concludes as follows, that "a short, simple operation gives almost the only hope of success, and the earlier the operation is performed the shorter and simpler it may be made."

(To be continued.)

Clinical Memorandum.

A CASE OF TRICHINOSIS.

SERVICE OF A. M. SUMNER, M.D.
REPORTED BY W. L. BURRAGE, *House Physician.*

J. McA., thirty-seven years old and single, came to the City Hospital, February 6th last, suffering with what he thought to be rheumatism. He was a native of Maine, a carriage-builder by trade, and came from a boarding-house at the North End. At the time of

[13] Med. News, May 26, 1888, p. 569.
[14] Med. News, June 9, 1888, p. 628.
[15] Med. News, June 9, 1888, p. 629.
[16] Am. Jour. Med. Sciences, Oct., 1887.
[17] Ann. of Surg., May, 1888, p. 329.

entrance he gave a somewhat meagre account of himself. The following history is made up of his statements and of particulars gleaned from two women and a male friend, who took care of him just previous to his coming to the Hospital. Family history negative. Previous history: Fever and ague seventeen years ago, but no return of the trouble since; no venereal and no rheumatic history; a constant smoker and a hard drinker at times; was in the habit of going on a spree about twice a month, or whenever he happened to have a little money. Although a carriage-builder by trade, he could turn his hand to almost anything. The last work he did was leather-finishing in the town of Peabody, Mass., where he had been living with his sister for several months. He led a roving life, for the most part travelling about from one town to another, and living in cheap boarding-houses. Several years ago he went as far West as Minneapolis, but for the last two years had not been away from the vicinity of Boston. Most of this time he was in Peabody and Boston, the only exception being a short trip to Maine last Autumn.

Present history: Patient had been in poor health ever since he returned from the House of Correction, where he spent two or three months last summer, but had complained of nothing in particular. Four weeks previous to entrance began to have pain in left hip and knee, with some redness and swelling of those joints. About a week later had pain, that ran across abdomen into the back and over the region of the breasts, the pain daily increasing in severity.

Upon arriving at the boarding-house where he was cared for previous to coming to the Hospital, it was noted that he made use of a cane in walking. He was in poor flesh and looked sick; ate very little besides tea and toast, and could not sleep; said that he was suffering from pains that were all over him, but most intense in his lower back and abdomen. This was just two weeks before entrance. During the next two weeks he was confined to the bed most of the time; he moaned and cried out to such an extent, especially at night, that his friends were obliged to remove him to a more secluded house, where he would not disturb any one, and later to the Hospital, because he grew no better.

When he arrived at the Hospital he had a temperature of 101.3°, pulse of 85, and respiration of 18. The urine was pale, acid; specific gravity, 1040; urates much increased in amount; albumen and sugar absent; the average twenty-four hours' amount for the first week of his stay in the Hospital was thirty-five to fifty ounces.

Physical examination showed a well-developed, poorly-nourished man of about five feet ten inches in height. Heart: apex-beat seen and felt in fifth interspace inside nipple line; area of cardiac dulness bounded as follows: above, third rib; on right, one inch to right of median line; on left, one-half inch outside nipple line. A double murmur heard all over præcordia and in the first and second interspaces to the right of the sternum; systolic murmur heard best at apex, diastolic over second right interspace and upper sternum; both heard in axilla, systolic more plainly; neither in the back; systolic heard also in neck; pulmonic second sound accentuated; an arterial pulsation, seen at bend of elbow; pulse that of aortic regurgitation. Examination of the lungs and abdomen negative.

No œdema anywhere; some tenderness on pressure over right shoulder and left hip-joints; no redness or swelling. At entrance, patient was put on a treatment of salicylate of soda, grs. xii, every two hours, and this was continued until the 9th. Under date of the 9th, there is a note in the records to the effect that since entrance patient had suffered severely from sharp, lancinating pains, starting in back, and running through cardiac and epigastric regions; also from pains in the thighs and legs; unable to sleep at night because of the pain; profuse sweating; pain only partially relieved by opiates; extreme tenderness on lightest pressure over whole surface of body, most marked over lower costal cartilages and in the flanks.

On the 8th a sphygmographic tracing of the pulse was taken, showing the characteristics of aortic insufficiency. Morphia, hot fomentations, antipyrine, and nitro-glycerine all failed to control the pain, although at times he got a little sleep. Potassic iodide in five and ten grain doses, t. i. d., for four days had no appreciable effect. On the 16th, patient was put on four grains of quinine, t. i. d. On the 18th this was increased to four grains four times a day, and on the 20th to seven grains four times a day. On the 18th there was no material abatement of the pains in the epigastric region; the pains in the thighs and legs had disappeared. There was no redness, swelling, or especial tenderness of any of the joints. The temperature, which had been rising for the last two days, reached 102.8° that evening, the highest at any time during the disease.

From this point the records are as follows:

February 21st. Patient states that he has always been fond of pork; it is his favorite dish. He last ate it in the form of fried bacon about one week before his admission to the Hospital. It was purchased at a shop in Causeway Street in Boston. The note goes on to say: extreme tenderness on the lightest pressure over whole scalp, especially on the left side of the head; tongue dry, white-coated on the edges; pupils equal, react to light and accommodation; patient somewhat delirious at night.

February 24th. Microscopic examination of a portion of muscle removed from the supinator longus, right forearm, failed to reveal the presence of trichinæ. To-day, tongue heavily brown-coated, dry, and cracked. Patient complains of acute pain on the slightest movement of his body; has lost much flesh; gets out of bed often at night, and requires restraint with sheets; intellect moderately clear during the day; countenance wears an expression of great agony.

On the 22d quinine was omitted, and from this time the only treatment was whiskey and the Hospital solution of citrate of iron and quinine in sherry.

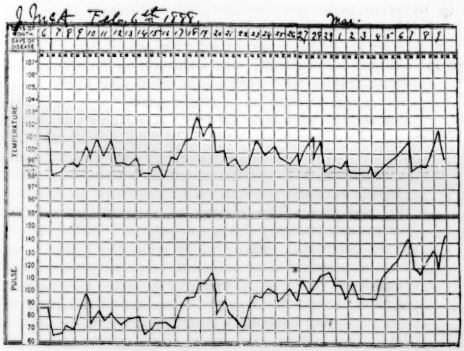
February 29th. A second examination of muscle, this time taken from the tensor vaginæ femoris, right thigh, failed to show trichinæ. (As there was no hook for the purpose, the muscle was procured in each instance by injecting a few minims of a four per cent. solution of cocaine subcutaneously and intramuscularly, and cutting down on the muscle. The operation caused no pain, the wounds were dressed antiseptically, and both healed by first intention.)

March 4th. General condition somewhat weaker daily; in a state of stupid delirium all the time; incontinence of urine and fæces. Patient continually rolls the bed-clothes into balls and throws them on the floor. Physical examination shows: pupils equal, re-

acting well to light and accommodation; cardiac murmurs as before; intensity of percussion resonance over both lungs in front somewhat diminished; in other respects, lungs negative. Abdomen negative; no paresis of muscles of extremities; tongue heavily coated; breath offensive; sordes on teeth and lips; universal tenderness on the lightest touch; much emaciation.

From this time till the 7th there was no change in his condition, except that he was not so bright mentally. When spoken to, his only answer was a moan. On the 8th he was manifestly weaker. He had become a living skeleton, cheeks hollow, limbs nothing but skin and bones. He lay in bed with knees drawn up, eyes rolling from side to side or half closed, muttering to himself while he rolled up the bed-clothes and threw them about.

This was his condition until the 9th, when he failed rapidly and died.



The bowels had been regular and the stools formed up to the 1st of March; after that there was considerable diarrhœa.

The patient took nourishment well, as a rule, though at times he would eat nothing for twenty-four hours. There was no vomiting. The urine, examined several times, was uniformly negative. The temperature and pulse are shown on the accompanying chart. No record of the respirations were kept, but they were at no time especially rapid or labored. Patient complained of pain on forced respiration; ordinary breathing was not painful.

Every effort was made to secure an autopsy, but without avail. After much persuasion, and just as the undertaker was removing the body, permission was obtained to take a piece of muscle. Accordingly, an incision was made over the seventh intercostal space on the right side, and a small portion of the intercostal muscle removed.

A few encapsulated trichinæ were found in this on microscopic examination. There were no calcareous deposits in the capsules.

— *Lawyer.* "Was the disease from which your husband died contagious?"

Witness. "No, sir; but it was awful ketchin'." — *Burlington Free Press.*

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

CHARLES HARRINGTON, M.D., ACTING SECRETARY.

Regular meeting, Monday evening, May 14th, at Medical Library, 19 Boylston Place. In absence of the regular Chairman, Dr. H. W. Williams was made Chairman, *pro tem.*

Dr. H. H. A. Beach reported

A CASE OF STRANGULATED HERNIA.

The strangulated hernia presented facts of unusual interest bearing upon the treatment of such cases complicated with undescended testicle. The patient was a young man who entered the Hospital with a history of a hernia, always reducible until forty-eight hours before his admittance. The day before entrance, taxis had been employed for four hours under ether unsuccessfully. When he reached the Hospital he was almost moribund. He was stimulated, etherized carefully, and a slight attempt made at taxis, to ascertain the condition of the sac and how much effusion it contained. It was found impossible to push the gut back, whereupon I made an incision into the largely distended sac, and found that it held a teacupful of bloody-colored serum; this having been evacuated, the finger could easily be carried into the ring and the intestine returned to the peritoneal cavity, there being no adhesions. The question naturally occurred: why had it been impossible to reduce the hernia before opening the sac? The reason was an undescended testicle, which was adherent to the sac on its inner side, the attachment or pedicle allowing the testicle to move easily inside and outside the ring. Of course, when there was a certain amount of fluid in the sac, the application of any pressure on the outside of the tumor would make the testicle, if it happened at that moment not to be in the hernial sac, act like a ball-valve, and so prevent the return of the distended gut. The moment that the sac was opened and the fluid evacuated the gut could be returned, and the testicle followed it easily. It is a condition that may occur in any hernia where the testicle is undescended, and teaches us that strangulated hernia complicated with undescended testicle *on the same side* is not to be subjected to prolonged taxis. An early exploratory incision is less dangerous. A few days after I saw a case with an undescended testicle on the opposite side from the hernia, the hernia being irreducible. No attempt was made at reduction, as there were no symptoms of strangulation.

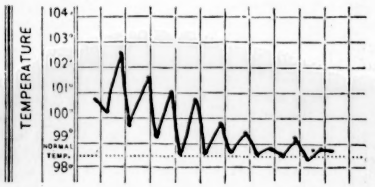
I have, also, to report

TWO CASES OF CARBUNCLE,

one in an elderly woman, and the other in an elderly man. The woman had already been so much prostrated by one carbuncle that it was desirable, if possible, to arrest the disease without the hæmorrhage and operative disturbance which naturally follows incision and scraping of carbuncles and removal of slough. With a solution of 1–2000 corrosive sublimate, I made subcutaneous injections into the border of the slough and inflamed tissue adjoining, and into

the mass of slough, with the idea of making an antiseptic wall *around* the area of sloughing tissue, to prevent the migration of micro-organisms into the healthy tissue, and to kill those within the wall.

There was a little sharp, stinging pain, and soon afterward a firm wall of lymph surrounded the slough. The carbuncle had existed five days and was spreading, but from the moment of injection the disease was arrested, and the slough separated rapidly with comparatively little pain. The second case is in the Hospital now. The diameter of the carbuncle was three and a half inches. It was treated in the same way, and is going on with an equally good result, and without anything else except the application of a cloth wet in a solution of sulpho-napthol and water, 1–50, applied afterward. The temperature has steadily diminished in both cases since the injection.



Of the different ways of treating carbuncles, I have seen a variety used by other physicians and surgeons, and have employed a number of them in my own private and hospital practice. I have never seen so immediate a response to treatment by any other method. So far as two cases go to prove it, simplicity, safety, and efficiency are its characteristics.

Mr. Rushton Parker, in a very interesting paper published in the *British Medical Journal* for March 31st, reports the successful injection of boils with corrosive sublimate and carbolic acid solutions, but, so far as I know, the plan of injecting the inflamed skin from the outside, so as to surround the slough, in addition to a thorough saturation of the latter with the antiseptic, has not been applied to carbuncles.

DR. FRANKLIN B. STEPHENSON said: This injection of carbolic acid in these cases reminds me that similar methods have been used to reduce adenitis in the form of bubo. I have tried it once with no success. I would like to ask the experience of those present in reference to such a method of treatment in the cases of bubo where there is apparently no specific cause, but only a strain or unusual exertion.

DR. R. H. FITZ presented a stomach from a patient of Dr. Beach. The case was one of

PERITONITIS FROM PERFORATING ULCER OF THE STOMACH.

It presents considerable interest with reference to the question of laparotomy for peritonitis. The patient entered the Hospital under the care of Dr. Abbott, and was for some time under his treatment for chronic ulcer of the stomach. The symptoms were sufficiently well marked to give but little doubt in reference to diagnosis, and after a certain length of time the patient, a woman, was relieved of the original symptoms of the ulcer. She recovered to such an extent that she was sent to the Convalescent Home. During her stay there an attack, apparently of follicular tonsillitis, occurred, from which she recovered in the course of a few days. She was able to go out and walk in the garden for two days, but on the third day, Wednesday, she was seized with a chill. This was followed, a few hours later, by pain in the hypogastrium, with elevation of temperature. The elevated temperature and the abdominal pain persisted; the latter became general. As the case was evidently one which required more active treatment than could be given at the Home, she returned to the Hospital. On the day of her return, Friday, there was no especial distension of the abdomen, but there was general abdominal tenderness and a marked elevation of temperature. On Saturday the same condition of things existed: the pain was worse, the constitutional disturbance greater, and she was then lying on the right side, with dulness in the right iliac region, the tenderness being greater on the left side than on the right. She was transferred, on Sunday, to Dr. Beach's care, with reference to relief by operation to the peritonitis. In the morning her condition was very much worse than the day before; her prostration was more extreme, the pulse being very weak, the abdominal distension considerable, with tympanitic resonance everywhere. There was a condition of stupor, partly attributable to the opium necessary to relieve the pain, but, at the same time, greater than the quantity of opium alone would explain. A consultation of several of the surgeons was held in the afternoon, at which some of the physicians were present, with reference to opening the abdomen. The history of the case indicated a peritonitis, probably from perforation. The question of the perforation taking place from the stomach or from the appendix, or caused by a pelvic process, was considered. A vaginal examination gave no evidence as to the existence of pelvic trouble, and the question essentially lay between a gastric ulcer and the appendix. The evidence in favor of a perforating gastric ulcer was to be found in the pre-existence of this disease, as indicated during her previous stay in the Hospital and the well-known likelihood of such a condition occurring in the history of this affection.

The possibility of a perforation of the appendix was to be found in the localization of the dulness, with the resistance, in the right iliac fossa, and the fact that the abdominal pain, according to her statement, started in the hypogastric region. It seemed probable, if the perforation occurred in the stomach, that the pain would have been, at the outset, in that region, with some sensation of tearing. Her condition, however, was so grave (she was evidently moribund at the time of the consultation) that a laparotomy was considered inexpedient, since this operation might be exploratory at the best, and, in case the appendix was not found to be the source of the trouble, a very extensive and prolonged operation would be required.

She died a few hours later, and the specimen shows the source of the peritonitis, which was fibrino-purulent. The inflammatory product was found in greatest abundance in the pelvis, and it is probable that the dulness found in the fossa on the preceding day was due to the gravitation of the liquid to that region. The stomach shows two ulcers, one on the anterior and the other on the posterior wall. The latter is the larger of the two, and has for its floor the pancreas. A perforation existed through the adhesions which united the stomach and pancreas, and this was prob-

ably the source of the peritonitis. In the anterior wall is a hole, now quite large, a quarter of an inch or more in diameter, and which is at the seat of the smaller ulceration. In the immediate vicinity of this hole the stomach-wall is thin, there is less mucous membrane, and there has existed an irritative process sufficiently prolonged to result in fibrous adhesions on the peritoneal surface. This rupture probably occurred during the examination.

The appearance presented by the stomach at once suggests that any operation would have been of very doubtful service, even had her general condition been more favorable; for the surgical treatment of this ulcer of the stomach would have demanded an incision through the wall of the stomach, that the posterior wall and upper surface might have been reached; and, even then, there was still another ulceration which might readily have been overlooked to be treated by incision and suture.

OVARIAN CYST.

Dr. H. H. A. Beach: I have an ovarian cyst here which Dr. Fitz was kind enough to say he would show; also two tumors of the breast, removed two weeks ago. The patient was fifty-nine years old, and was sent to the hospital by Dr. Gunter, of Charlestown. For two years after the cessation of menstruation the abdomen continued to swell, until at the time of entrance to the Hospital she measured forty-eight inches at the level of the umbilicus. There had been no disturbance from the swelling but frequent micturition. The legs and feet had been swollen but that symptom had disappeared after being confined to the bed for a short time. One wave of fluctuation could be felt throughout the abdomen and on this account a number of gentlemen who examined her considered the fluid ascitic, or ascitic complicated with ovarian disease. The unquestionable resonance of one flank determined me to give her the benefit of an exploratory incision, when the large amount of fluid was found in a single cyst, completely enveloping the multilocular and more solid portions of the growth. The amount of fluid was eighteen quarts, which together with the solid growth weighed thirty-eight pounds. The pedicle was very large and thick; it had the width and thickness of the open palm of a man's hand. It was easily treated by a clamp which I have invented and have used successfully in a number of cases. As you will see, it is made with the idea of compressing the pedicle by a broad surface, so that it becomes reduced to its toughest elements by squeezing away from the compressed surface the softer elements of the pedicle, there is after that no chance for a shrinkage of the pedicle following the application of the ligature and consequently no danger of hæmorrhage. The clamp is made of three separate parts joined by a pin that perforates each hinge — the jaws are closed by three separate screws—after the compression has been made, and the tumor removed, the severed end of the pedicle is thoroughly cooked with the actual cautery, the central pin is unfastened and the central section withdrawn, the pedicle is now seen compressed to one-fourth or less of its original thickness. A stout ligature is now passed by transfixing the pedicle twice and tying the knot temporarily, the outside section is then removed and the ligature thoroughly fastened, the thin section is removed and the ligature once more tightened and cut short, then dropped into the abdominal cavity. The patient made a recovery in nine days.

Dr. Fitz: The cyst is a multilocular cystoma, of the glandular variety, with chiefly colloid contents. The larger cavity contained watery fluid. This difference in the composition of the ovarian cystoma is not uncommon, the smallest cysts having often colloid contents, while the larger contains a thin material.

TUMOR OF THE BREAST.

Dr. Beach: The next case was a tumor of the breast, the patient aged sixty-five. The tumor was about the size of a fœtal head, with no axillary glands, and I report it on account of its being an interesting specimen of breast tumor, and as another instance of union by first intention, using the quill drainage-tube. It makes the sixth case that has healed by first intention successively. This one was the largest tumor of the series; three of them were cancers, with cancerous glands in the axilla which were removed. The skin, before doing anything in the way of operation, was scrubbed daily with corrosive solution and sulpho-naphthol, 1–50. Boiled silk ligatures were used. The usual antiseptic precautions were taken at the time of the operation, and it was afterward dressed with iodoform gauze, and covered with salicylic cotton. There was nothing unusual about the operation. There were no glands in the axilla in either case. As an instance of what can be done with quill drainage, I show here the size of the quills that can be found in the shops, This one is large enough to drain an ovarian cyst. It is a fact that they do not make so much trouble in the way of after-treatment of the wound as the rubber drainage-tube. They do not delay union and the tube opening closes more rapidly than the one left after a rubber tube.

Dr. Fitz: The anatomical interest of these specimens lies in the fact that they are rather an exceptional variety of tumor of the breast, and that they represent what the late Dr. J. B. S. Jackson frequently called attention to, and which is familiar to all of you, the occurrence of the same variety of rare tumors within a short period of time. The larger was removed two weeks ago, and is twice the size of the smaller. The tumor is apparently simply an enlargement of the breast, analogous to what has been repeatedly described as a chronic mammary hypertrophy. The appearance of the gland on section shows a homogenous gray and translucent appearance, with fissures, irregular, and very often Y-shaped. In the smaller of the two breasts it will be seen that the depressions are deep, with the lobules of the tumor projecting into them. This is the condition which gives evidence of the intra-canalicular growth of the tumor, so that the lobules, projecting, press upon the ducts of the glands, which become elongated, and not infrequently tortuous. The essential nature of the tumor, of course, depends upon the structure of the new-formed tissue which causes this dilatation of the gland ducts. In both cases the structure was essentially cellular, in one the cells being round and in the other rather spindle-shaped, and with comparatively little intercellular substance. They are, therefore, sarcomata presenting the intra-canalicular form of growth. The term sometimes applied to this growth is that of cysto-sarcoma.

Dr. James J. Putnam read a paper entitled

PERSONAL OBSERVATIONS ON MULTIPLE NEURITIS,

and gave a provisional report of a fatal case, probably

to be classed as of infectious origin, which he had seen in consultation with Dr. M. A. Morris, of Charlestown.

The histological examination was not yet fully complete, but sufficiently so to be of interest in this connection.

The patient was a healthy man in the prime of life, and the only exciting cause known was exposure dura rain-storm. The duration of the disease had been one week, death occurring from asphyxia, probably of pulmonary origin. The illness began with prickling in the hands and feet, weakness of the legs and arms, and an especially great impairment of the motion of the left arm at the shoulder. The paralysis spread steadily and became eventually almost universal, though nowhere absolute. There was moderate tenderness on deep pressure among the muscles of the legs and arms.

At the autopsy, which was performed by Dr. R. H. Fitz, the spleen was found enlarged, and the lungs studded with hæmorrhagic patches. The brain, spinal cord, and medulla were removed for further examination. Portions of the anterior crural and other lumbar nerves, the vagus, and the left axillary plexus were removed, and examined later, both in osmic acid and after hardening in Muller's fluid.

Changes similar to those described below were everywhere found, but much more markedly in certain parts of the brachial nerves than anywhere else. These changes consisted (1) in excessive swelling, or, on the other hand, atrophy and destruction of axis-cylinders, with a very variable amount of change in the myeline. In some primitive nerve-bundles scarcely an axis-cylinder was to be seen; (2) in evidences here and there of cell activity, affecting both the white cells of the blood and the endothelial and connective tissue cells of the nerve itself.

No hæmorrhages have as yet been found, and no large number of mastzellen such as Rosenheim found in his case.[1]

The pieces of the nerves removed were, however, unfortunately not very long, and the peripheral expansion was not examined except in the case of some of the diaphragmatic filaments of the phrenic, which were not much, if at all, diseased.

Parts of the left deltoid muscle were examined, with the result that the fibres as a rule were found healthy, while here and there there was one where the transverse striation had disappeared.

In seeking for the cause of the great swelling of the axis-cylinders on longitudinal and torn preparations, it had been found that as a rule these swellings were situated close to the annular constrictions of the nerve fibres. Sometimes the swelled axis-cylinder filled the entire space within the sheath, and vacuole formation had taken place in them, besides destruction of the myeline for a considerable distance. In short, the change seemed, on a large scale, identical with that described by Ranvier as occurring in nerves exposed to the action of water and other fluids.

The idea naturally suggests itself that poisons (like nutritive fluids) enter the nerve fibres in this way, eventually destroying them, and the speaker is engaged on a series of experiments to test the behavior of nerves, in this respect, when exposed to poisonous fluids surrounding them or injected into the blood-vessels.

[1] Arch. für Psych., etc., Vol. XVIII.

DR. FOLSOM: I have been exceedingly interested in this paper. I have little to say in addition to anything that Dr. Putnam has said. I find, on looking over the third service records at the City Hospital, there are at the present time fifteen cases of general neuritis in the wards. These fifteen cases occur in a total of between 240 and 256 patients — about six per cent. That is a very large proportion, but it has been known for many years that the City Hospital had a service for diseases of the nervous system, and such cases have been gravitating there.

The first case that I have to speak of is a woman of thirty-five, with universal neuritis of the arms, trunk, abdomen and legs. The disease appeared suddenly after exposure to wet, and was attended with the usual symptoms, marked loss of power, inability to walk well, excessive tenderness over the course of the peripheral nerves, etc. Thus far I have not been able to ascertain any special cause for this particular case, and I suppose it to be idiopathic. Of this case it should be said that there is a slight amount of dulness at the apex of the left lung, slightly increased voice, and prolonged expiration. Whether it is a beginning phthisis or not, and the neuritis belongs to that class, I am unable to say. There are no râles, and the patient's general condition is bad. The sputa have not been examined for bacilli.

My impression is that there are two groups of idiopathic cases, first those that come on in a slow way, as in subacute rheumatism, and, second, those which Strümpel speaks of as beginning with chill, fever, temperature of 102–103, typhoidal appearance, and slightly enlarged spleen.

The next case is of phthisis involving both lungs, with ulceration of the vocal cords. There are the characteristic symptoms as in the first case, excessive tenderness over the course of the nerve, etc., and also such extreme pain that the patient has to be kept under opiates.

There is also a case that is interesting from the point of view of differential diagnosis between peripheral neuritis and myelitis. My impression is that in alcoholic cases the spinal cord and peripheral nerves are both affected; and, of course, possibly in cases due to other causes. When I first saw this case the diagnosis was perfectly clear. It was a transverse lumbar myelitis, but I am told that when the case entered the hospital the symptoms were by no means clear, and there was a sense of numbness, of loss of power, a great deal of pain in the legs, and excessive tenderness over the trunks of the peripheral nerves.

It is a rather unusual symptom, I suppose, in transverse myelitis, and it seems to me that the only explanation is that the neuritis was only an accidental complication of the myelitis, or possibly due to the same cause. But the neuritis has not pursued a chronic course, the symptoms referable to that having chiefly disappeared, there is very little pain left, there is scarcely any tenderness, and although there is absolute loss of sensation there is very little atrophy of the legs, not the marked atrophy that you get in peripheral neuritis, but the condition which one gets in transverse lumbar myelitis.

There are four cases which I suppose to be purely rheumatic; whether more than the sheath of the nerves is involved I do not know. Two of them were young girls who came into the hospital for so-called rheumatism. It was found that they could walk only

with the very greatest difficulty. On examination there was very little appearance to account for it. There was very slight swelling of both feet, and a very slight red blush characteristic of rheumatism, but not enough to account for so great disability. There was excessive tenderness over the posterior tibial nerves, even a moderate pressure producing severe pain. Under the proper treatment for rheumatism, salicylates and alkaline, the pain and swelling disappeared, and also the pain on pressure over the nerves. The third case which I considered to be rheumatic was similar to the other two, except that the pain has recurred once after disappearing. The fourth case which I suppose to be rheumatic is a German, who came in with the ordinary symptoms of rheumatism. He spoke only German, and did not make the fact understood that, although he had acute rheumatism, what troubled him most was a feeling in his calves, as of pulling something apart. He had intense sensitiveness to pressure upon the posterior tibial nerve, and the same with some of the others.

There was one case of acute cerebro-spinal meningitis which is interesting in connection with the symptoms which were spoken of in a paper at one of the meetings a few weeks ago. It proved to be a typical case of cerebro-spinal meningitis, although the diagnosis for a while was in doubt between that and the tubercular form. The patient had not only extreme pain in flexing the thigh and extending the leg, but some pain on any movements of the leg, and while she was in the condition of extreme stupor it was a little difficult to entirely account for it; yet as soon as the intelligence in a degree returned it was found that this was due to peripheral neuritis, which, as Dr. Putnam says, is quite common in the various acute diseases of that type, typhoid fever particularly.

There are four cases of alcoholic origin. Two of them have enlarged livers. Whether it is hypertrophic cirrhosis or not I am not sure, but like the other cases that have lasted some time the knee-jerks are entirely gone in these two, and there are the usual disabilities, which I need not repeat.

These are in women. The other two cases are in men. One of them is just beginning to walk now, and and he has the characteristic gait of neuritis, which distinguishes it from locomotor ataxia.

I have seen cases which have been diagnosed as posterior spinal sclerosis, when the later history proved them to be peripheral neuritis without pain or tenderness as in this case. The patient drops his toes slightly when he walks. The fourth alcoholic case is rather interesting from the complication of a condition of extreme dementia which is sometimes confounded with the last stage of general paralysis of the insane. The history is very often obscure, and in this particular case there was no tenderness over the course of the nerves, unless the patient was moved, and he was too stupid to indicate whether he had any numbness or not. He came into the hospital in a state which reminds one of the terminal dementia which we see in the insane asylums, with quite marked emaciation of the legs, and, of course, inability to stand or walk. As I say, there was no pain at all in the legs, but the most exquisite pain on even slight pressure over the course of the nerves. These cases, although their mental state somewhat resembles the condition of terminal dementia from organic disease, are very easily differentiated from them by the mere expression of the face. One sees, in comparing them with a case of dementia from organic disease, that the muscles of expression have not absolutely lost their power, and that there is not that entirely vacant and staring expression which is shown so well in the composite photograph by Dr. Noyes which I showed to the Society some time ago.

The case of post-diphtheritic paralysis is interesting. This patient came into the hospital three days ago — a very marked case of the kind. There was an absolute loss of power in the hands and legs. He talks a little above a whisper, uses his hands incompletely, and walks very badly indeed. He has the characteristic numbness in the extremities, and all the other symptoms of the disease except pain. He has absolutely no pain whatever. The interesting feature in regard to the case, from the point of view of diagnosis, is that the sensory symptoms and the motor symptoms of the two legs are precisely alike except in one point, and that is in the left leg, the other symptoms being precisely like those in the right. There is very great tenderness on pressure over the nerve trunks. In the right leg, with the other symptoms identical, there is no tenderness whatever, illustrating the fact which Dr. Putnam speaks of, that cases do occur not only without pain, but also without undue sensitiveness on pressure over the nerve trunks.

Another case is rather an interesting one from the fact of the neuritis being unilateral, and associated with organic disease of the brain. This is a gentleman who has organic disease of the brain, the nature of which cannot be as yet determined, in the region of the fissure of Rolando on the right side, and marked loss of power in the left arm and left leg, not, however, amounting to absolute paralysis. He has complained of very severe pain in these limbs for several days, and it is found that there is a marked neuritis there. That is to say, pressure on any one of the nerve trunks causes very severe pain, the right side being entirely free. In these cases differing from the others, the knee-jerk is very much exaggerated, and that of course is due to descending degeneration of the motor tract.

There is another case which is somewhat like the one I have just reported, in the fact that I have not been able to discover anything throwing any light on the etiology. Very often, cases of peripheral neuritis in the Hospital are of syphilitic origin, but, unless this case of which I am about to speak is of syphilitic origin, I do not know to what cause to refer it. The patient is very much emaciated, the pain is very great, and the tenderness on pressure is extreme. He is able to walk, but with very great difficulty, and his gait simulates a little more the gait of posterior spinal sclerosis than ordinarily in cases of multiple neuritis. The power of the extensors is not entirely gone, and I find, on questioning him carefully, that he holds up his toes by very great effort, because the least motion causes such extreme pain. I have never seen a case precisely like this before in the very widespread distribution of the tenderness on pressure, which is universal in the legs. It is almost impossible to find a place where there is not some tenderness, but over the main trunk the sensitiveness is so much greater than elsewhere that I think there can be no doubt in regard to the character of the disease being neuritis. He is now taking a drachm and a half of the iodide of potassium a day, and will soon take double that amount,

and is improving. He denies any venereal antecedents.

I thought these cases might be of interest, although there are not represented all the various forms which occur, due to various causes, they show to what a variety of causes peripheral neuritis may be due, and the difficulty, in a great many cases, of establishing the etiology on a satisfactory basis. Dr. Putnam spoke of one case previously seen by me, in which the trouble was confined to the upper arms and shoulders, that he saw a number of years ago. I have since seen two cases precisely like that. The case that he referred to was a carpenter, who, in a cold November rain-storm, worked pretty much all the forenoon assisting in putting out a fire, getting thoroughly wet there, and remaining all the evening with his wet clothes on his shoulders, having changed all his other clothing. The second case was a man who got drunk and lay several hours with his shoulders exposed, and the third was somewhat similar. The subsequent history proved to be like that of the first. It seems to me that these cases show that the fact stated in the text-books, that the anterior poliomyelitis of adults differs from the anterior poliomyelitis in children in that the prognosis is much more favorable, is not true, and that it is probable that errors in diagnosis had been made, and that the cases were really cases of multiple neuritis, and got well, although supposed to be anterior poliomyelitis.

DR. S. G. WEBBER said: I have been very much interested by what Dr. Putnam has said, and the cases that Dr. Folsom has reported. I think we are gradually coming to recognize what an extensive disease neuritis is, how it comes in as a complication and as a distinct disease in so many cases which have previously been ascribed to other causes. It is so late, I will not multiply the number of cases reported. I will only say a few words in regard to the pathology in a case that I had at the City Hospital, where almost all the nerves were affected, and which I reported in 1884. I examined the nerves, preparing them with osmic acid. I think that for the examination of nerves this is especially valuable, inasmuch as the myeline is colored black, and each minute drop of myeline receives its color, so that the changes are made very evident and very clear. There were two classes of change which I found; I mean in the first stages of the change. As Dr. Putnam has drawn the constriction of Ranvier, one was near that, the primary change; the myeline beginning to divide into segments near this constriction, the first appearance of change being a separation into globules and a separation of the myeline away from the constriction, and the pushing of it away in much the manner as Dr. Putnam has intimated.

The other form was where the change had occurred around the nucleus in the centre of the cell. The first change in the myeline occurs near the nucleus, not at the constriction, the myeline being comparatively complete at the constriction of Ranvier, dividing up into an appearance as though it was becoming segmented near the nucleus. The disadvantage that I found in using osmic acid in preparations was that afterward the carmine did not discolor very clearly the axis-cylinder or the nucleus. The coloration was very faint, although they did take the carmine to a slight degree. The segmentation of the myeline goes on until the whole of this node is divided into small segments of larger and smaller size, and then it is absorbed, and we have, finally, simply a few drops of myeline scattered about in the sheath of the nerve, the axis-cylinder being lost and the sheath being also reduced in size. That is the extreme limit.

Soon after having seen these cases, I was interested in this matter of neuritis, and tried some experiments at the Medical School on rabbits and guinea-pigs, producing neuritis artificially. I had laid out an extensive plan of experiments, which I did not have time to carry out. I think that nearly every case of artificial neuritis, where the inflammation was evidently active, I found a change near the constriction of Ranvier, not in the centre of the cell of the nerve-fibre. It did not seem to be due altogether to the preparation of the nerve in osmic acid; it was more like what I have found in the beginning segmentation in myelitis. Possibly a few occurred, as in the second variety mentioned before, near the nucleus of the nerve-cell. At a distance from the point where I applied the irritation the nerves were very much degenerated. If the animal lived long enough and I got secondary changes, such as you get when the nerve is cut, these are secondary changes, the nerve-fibre being reduced, as in the case of disease, to a sheath filled with small particles of myeline.

DR. BULLARD: I would like to ask Dr. Putnam whether he has known of any case in which the auditory nerve is affected. I had a case in the Hospital a month or two ago, in which the man came in with very severe neuritis, with alcoholic and syphilitic history. The man was very low; he was in the Hospital for about six weeks. About two weeks before his death he was suddenly attacked with deafness, almost total, in both ears, and the ears were examined by Dr. Spear, who said that nothing could be found to account for the deafness. I am sorry to say that I believe they were not examined with the tuning-fork, and it seemed probable at the time that it might have been due to an affection of the nerves. I would like to ask that question.

DR. PUTNAM: I have never heard of such a thing, and I think it is an interesting suggestion.

DR. MORTON PRINCE: The hour is so late, Mr. President, that I will not take up the time with any extended remarks. I only wish to call attention to what may prove to be a very interesting fact. Though what I am going to speak of may be mere coincidence, it may throw some light on the etiology of multiple neuritis. I remember that in 1884, when Dr. Webber reported his cases, there was an unusually large number in the Hospital. Now it so happened that at the same time there was an epidemic, among the horses of this city, of a disease characterized by paralysis. I had a horse at the time affected, and was able to observe the disease. Now it happens again, this year, that there is a large number of cases of neuritis in the Hospital, and, again, there is a disease prevalent amongst the horses characterized by paralysis, and similar, so far as I have been able to observe, to the epidemic of 1884. The disease has each time been diagnosed by the veterinary surgeons as meningitis, but I have been unable to understand the grounds on which the diagnosis has been based. It seems to me, all things considered, that the disease is more likely a multiple neuritis, but it will require a *post-mortem* to establish the fact. If it should turn out to be so, considerable light may be thrown on the

etiology of multiple neuritis. I think Dr. Webber suggested to me, in 1884, that it might be this disease.

Dr. P. C. Knapp: I have not very much to say in regard to Dr. Putnam's very interesting paper. I was interested especially in the case that he reported of the woman who had the oculo-motor paralysis, because I was reading only a few days ago about a case, which seemed to be fairly well authenticated, of a neuritis which affected the different cranial nerves, one after the other, beginning with the third and fourth, I think, then having an optic neuritis, and then neuritis of the seventh, with typical facial paralysis. In my own experience with these cases of multiple neuritis I have not found the exaggeration of the knee-jerk, unless, as in the case which Dr. Folsom spoke of, which I saw with him this morning, there is also some other cause which might well explain the exaggeration. Of course, where the nerve going to the quadriceps extensor is not affected, there is no particular reason why the knee-jerk should be affected; but in the ordinary cases, where these nerves are involved, it seems to me that, unless there is some other fact that comes into play, the knee-jerk is either diminished or absent.

In regard to Dr. Prince's suggestion about the affection in horses, it seems to me hardly fair to consider the great prevalence of multiple neuritis now as an indication of its infectious origin, from the fact that there are so many causes, some alcoholic, some rheumatic, and others due to other infectious diseases or mineral poisons. It does not seem to me that, with so many different forms of neuritis, their frequency can fairly be attributed to one infectious cause.

Recent Literature.

A Text-Book on Surgery, General, Operative, and Mechanical. By John A. Wyeth, M.D., Professor of Surgery in the New York Polyclinic, Surgeon to Mount Sinai Hospital, etc. New York: D. Appleton & Co. 1887.

This text-book, comprising some seven hundred and twenty-five pages, profusely illustrated, is intended to present surgery as it exists to-day. In dealing with such a broad subject, the author has been obliged in many instances to omit what might well be deemed important subjects. For instance, neither pyæmia nor septicæmia are treated of in the volume; this, we suppose, is in part due to the practical obliteration of these affections by antisepticism, and then, again, by the imperative condensation, which has been admirably accomplished, in a work of this magnitude. This condensation has necessitated positive assertions on the part of the author, which would have otherwise been tempered by the experience of others. In a few instances we feel that the author's statements should be modified; for instance, ether is certainly not to-day recognized as *the* anæsthetic, to the practical exclusion of chloroform, for there still exists a large part of the profession who fail to recognize ether's superior advantages. The plates, many of which are colored, are worthy of especial mention. Dr. Wyeth has admirably succeeded in producing a hand-book for students and practitioners.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 13, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States and Canada; $6.00 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 Boylston Street, Boston, Mass.

SERVIA'S SANITARY SYSTEM.

In these times of effort toward a thorough, a rational supervision and control of matters affecting the public health, physicians and others may be interested to know the *schema, in re*, formulated by a very young member of the comity of nations.

An experienced economic observer and philosopher (De Laveleye) reports that, in Servia, the "general sanitary council" of seven doctors is a scientific consulting body for the State: its duty is to study and regulate measures adopted by the "sanitary department," whose functions are executive. The "sanitary department" is under the authority of a surgeon-general, with an inspector-in-chief, secretary, two chemists, and a veterinary: its sphere comprises everything relating to health, including even the food of the people: obligatory rules in regard to the diet of working-men are numerous and minute.

The national administrative *cadre* is paralleled by the medical. The *préfet*, or departmental governor, has the aid of a doctor, correspondent in grade, and nearly as well paid: the heads of districts and communes have, likewise, medical advisers, receiving the same salaries. Midwives and veterinaries are subordinated to this "department." In each town of importance the physician has a right to form part of the municipal council or board of aldermen.

The country is, therefore, as to hygiene, in the hands of medical men — a national board of health, with proper sub-officials — empowered to inspect and dispose all things concerning the physical well-being of mankind and of domestic animals.

We instance a few details by way of illustration: Every child must be vaccinated between the third and twelfth month; again when leaving the primary school; and once more when twenty-one years of age. This operation, free and compulsory, is performed from May 1st to September 30th, under superintendence of the *préfet* and departmental surgeon, in presence of the mayor. The proper medical officer must

inspect inhabited houses, and remove causes of illness arising from poor food and water, defective drainage, and from customs relating to births, burials, etc. Buildings where there are contagious diseases have descriptive labels affixed. (A similar rule is followed in Holland.)

In the care of public health, the government has not feared to make regulations forbidding a secular usage closely resembling a religious rite. Certain church followers had the habit of carrying their dead to the cemetery in an open coffin, the face and body covered with flowers: under the new *régime* a closed funeral case is requisite. The question of cremation — a safer mode for the oxidation of organic substance that must decay and may spread disease — appears less urgent for consideration there than in our own territory. Strict and detailed directions exist to stop the progress of infectious maladies, both on the frontier and throughout the kingdom.

Some of the so-called civilized nations have done much to improve the qualities of race in domestic animals — the lower animals, as sometimes called; whereas the procreation of nature's highest kind of life, whereon intellect has been grafted (or wherein it is developed), is left, for the most part, to unreasoning impulse — with results that every informed and thoughtful mind can but deplore. In this newly-formed European commonwealth, however, the function of the departmental doctor is to trace how marriages are made, if they produce hereditary affections, what is the average number of children to each union, and whether there are limiting causes. Under penalty of disciplinary punishment, the medical officer is to obtain from the *préfet* measures to abolish, in workshops and private houses, "everything that may injure health."

It is a subject for serious thought whether it be wise to place citizens under the tutelage implied by such an extensive officialism. Nevertheless, so complete a system, earnestly applied, would without doubt save from much pain and sorrow not only the average man, but also those who, in a sanitary and physiological point of view, ought never to have been born.

THE ASSOCIATION OF GENITO-URINARY SURGEONS.

THE union of several gentlemen from various parts of the country in an association devoted to the study of genito-urinary diseases seems to awaken the mirth of various medical periodicals, and lately the *London Lancet* has taken occasion to read the whole profession a little lecture because of the existence of this society. Doubtless it may seem to many at first thought, that this particular society is superfluous, and its field limited. A few sentences from the *Lancet* will show the animus of its remarks.

"The expression 'genito-urinary surgeons,' which does not seem to us a happy one, indicates the disposition to erect a new specialty which we trust will be reconsidered. . . . It is not a wholesome sign, this tendency for a group of men to fly off from the great body of their brethren and put a special label on themselves. Where is it to stop? Is syphiloma of the vulva to be regarded as something apart and special; or can it be separated without harm to the general conception of the case in which it occurs?"

In a succeeding number the *Lancet* again refers to the subject:

"Last week we directed the attention of our readers to an illustration of the portentous development of specialism in the title of an association soon to meet in Washington under the name of Genito-Urinary Surgeons. This group of gentlemen, including, we notice, some of the most honored names in the history of American medicine, have it is true, as we showed, with a delightful innocence, appropriated a somewhat large field for their special preserve, including diseases as widely apart as syphiloma of the vulva and interstitial nephritis. If the system of specialization is to go on unchecked, there will not be many more September Congresses at Washington before the Association of Genito-Urinary Surgeons will be broken into a hundred fragments, and we shall have yet more undignified uses of specialism," and it predicts the formation of other associations with "still more unsavory" names.

Now this JOURNAL is not inclined to differ from the *Lancet* in its apprehension of increasing specialties, and it is in no sense authorized to speak for the Society of Genito-Urinary Surgeons; but the views of the English journal seem superficial and one-sided, and deserve a word, perhaps not of justification, but of explanation, in behalf of the Society.

There are scattered through the different cities of the world a few medical men whose practice lies in great measure in diseases of the urinary organs, of whom Sir Henry Thompson may be regarded as a shining example; and in the United States such men exist in fair proportion, and they have earned the *Lancet's* contempt by associating themselves together for the study of the diseases in which they are specially interested.

Genito-urinary surgery has become a separate branch of instruction in many medical schools, because, to make instruction thorough, it is necessary to subdivide general surgery.

This Association includes many men who give instruction in genito-urinary diseases in these various medical schools: some of these gentlemen are also particularly interested in syphilis: some are well known as dermatologists; some would be willing to be called specialists; some would resent the name. Some of them might be said to be specially interested in diseases peculiar to the male sex; some of them are general surgeons; others still do a general practice. Their association is not for the purpose of establishing themselves as specialists, but for mutual study and information; or, in the words of their Constitution, "to promote the study of genito-urinary and venereal

diseases," it being expressly stated at the first meeting of the organization that the study of syphilis shall be included in its work.

Now, notwithstanding the sneers of the *Lancet*, that seems to many honorable men a perfectly legitimate field of study. Mutual acquaintance and discussion will not make these gentlemen less efficient as instructors, or less valuable to the community.

The name is a little misleading in that it fails to show the full scope of the Society. The *Lancet* appears to be imbued with the idea that because a syphiloma of the vulva is to be reported at its coming meetting, the Society is so constituted as to consider syphilis as appearing on the genital organs, and not elsewhere.

The *Lancet* can hardly have spoken with its best thought when it intimates that the name is "unsavory." The titled individual who refused to know Sir Astley Cooper because he would examine his rectum for a guinea might have despised men who would adapt the principles of optics to an inspection of the urinary reservoir, but it is a surprise to find such language in a journal which is devoted to the interests of the medical profession. The *Lancet* must occasionally blush as it reads its own pages. Progress is made by men who study comparatively small fields. Men who devote themselves to comparatively narrow limits, and so systematize and condense the knowledge of that field that it can be readily appropriated by others, help the advance of general medicine.

A MATTER OF DIAGNOSIS.

A suit of great interest to medical men has been brought in the courts of Rhode Island by a Mr. Larkin, proprietor of one of the hotels at Watch Hill, R. I., against Dr. Samuel O. Vanderpoel, of New York, for alleged damage to the plaintiff's business by reason of a diagnosis of scarlet fever made by the defendant in a case of a child staying at his hotel. Dr. Vanderpoel was called to see the child, diagnosticated a mild case of scarlet fever, and advised that the child be removed to a cottage belonging to the proprietor, so as to be isolated from the guests. This recommendation was not complied with, and the child's nurse continued to go to the servants' dining-room. The diagnosis becoming known, a general exodus of guests took place, and the house, which contained a great many families with children, was soon nearly deserted. The damage in the suit is laid at $12,000, though it is difficult to see on what grounds the case is to be urged. Dr. Vanderpoel's diagnosis, it is said, was confirmed by two other physicians, though it was disputed by one practitioner who saw the case in the interest of the landlord. The manner in which the notice was served upon the defendant was particularly aggravating, the sheriff declining, it is said, the bail that was offered, and expressing his intention to lock up the doctor. The exceedingly delicate position in which a physician is placed who is called to a case of infectious disease in a summer hotel is well illustrated in this case, but if a man is to be subject to a suit every time he makes such a diagnosis, it is time the profession knew it and protected itself. It is reported that Dr. Vanderpoel will bring a counter-suit against the hotel man for damages.

MEDICAL NOTES.

— Yellow fever has increased in Jacksonville, Florida, to a marked degree during the past week, the average of new cases daily being 50 or 60. The total up to 6 P. M., September 9th, was 604, deaths 73. Among those prostrated by the fever is Hon. H. A. Leugle, chairman of the committee on sanitation of the citizens' association, who has worked indefatigably since the outbreak of the fever. There remained in the city September 7th, 13,757 people — 3,945 whites and 9,812 blacks. Of these 10,375, mostly colored, are unwilling to leave, and 3,495 are without means. It is expected that 2,000 or 3,000 will leave in ten or twelve days. The complete depopulation of the city is impossible, and those without means can hardly be provided for in the refugee camps under a month or six weeks, during which time, it is feared, the epidemic will have done its work and hundreds of lives been sacrificed. The negroes are loth to leave, being told by politicians that they will lose their votes by a change of residence.

Ten cases of yellow fever are reported at McClenny in Baker Co., Fla., and one death from black vomit. Pensacola and Marianna have quarantined against the whole of Baker County. Montgomery, Ala., will follow their example.

Surgeon-General Hamilton, of Washington, at the suggestion of the President, has taken charge at Camp Perry in person, relieving Dr. Guiteras.

The officials of Jacksonville have made an urgent appeal for aid, which has been promptly responded to by some of the northern cities.

The Adams and Southern express companies have offered to transfer free of charge all supplies, money, contributions and flowers sent to the city for the benefit of yellow fever sufferers. Supplies should be addressed to Judge Loton M. Jones, chairman relief committee, and money to J. M. Shumacher, chairman finance committee. Quite a number of "Red Cross" nurses have arrived from New Orleans. No unacclimated person will hereafter be allowed to go into the city.

Despite the fact that there has been some suffering for lack of proper nursing, northern nurses are not specially desired, because they have not had the experience with the disease which is so desirable. It is said that there are plenty of capable, well-trained yellow fever nurses in Savannah, Charleston, Mobile, New Orleans, Galveston and other southern cities who are willing and anxious to do duty at the bedsides of the unfortunate people of Jacksonville.

— Hamons's disinfecting lotion for utero-vaginal injections is given by the *Monde Pharmaceutique* of June 5, "as it possesses characteristics of excellence which make it desirable as a summer toilet article:" Ac. salicyl and ac. thymic āā gm. 2; ol. ambra grisea, gtt. 20; ess. vanilla, gtt. 30; alcohol at 90° gm. 25; cologne water, gm. 50; aq. dest., gm. 300. It may be used from one to four times in 24 hours. — *Pharmaceutical Record.*

— A contemporary credits the following to W. S. Gilbert: A friend was bewailing in his company that his wife had just presented him with triplets, all girls. "What am I to do with them?" asked the poor man, "I don't even know what to name them." "Oh," said Mr. Gilbert, "call the first Kate, the second Duplicate, and the third Triplicate."

— A story comes from England which is not without its pathetic suggestion, especially to the medical man who has seen in elderly people the fear of mental decay and the suspiciousness with which they sometimes look for it in their contemporaries. The story was told by the late English portrait painter, Mr. Frank Holl, who, while painting the portrait of Mr. John Bright incidentally mentioned that he was about to perform the same operation for Mr. Gladstone. "It must be a very painful thing for you, Mr. Bright," he hazarded, "that after all these years you should have found cause to sever your connection?" "Indeed it is," responded Mr. Bright, with a sigh; "to think that, after we have trodden the same path together, shoulder to shoulder and hand in hand, we should be forced apart in the evening of our lives! And by what? By a bogey that has risen up within him and is beckoning him away from duty and sense — by a Frankenstein. Do you know, Mr. Holl, I seriously fear that my dear old friend's mind has really become radically undermined?" When he was at Hawarden painting Mr. Gladstone, the subject of the artist's portrait of Mr. Bright cropped up. "Ah!" said Mr. Gladstone with much interest, "and how did you find him?" "Fairly well, and he spoke very affectionately of you, Mr. Gladstone." "Did he, indeed?" replied the sitter, sorrowfully; "did he, indeed? That was a cruel blow. That after a lifetime of mutual esteem and of good work undertaken and carried through together, we should be divided on so clear a question. Tell me, Mr. Holl," — and here his mouth twitched, for he was evidently struggling with great emotion — "tell me, did you notice anything in the manner of my old friend which would lead you to believe that his reason was becoming in any way unhinged?"

NEW YORK.

— A large number of citizens and tax-payers of Jersey City were present September 6th at a meeting called by the Board of Works for the purpose of discussing the water-supply of the city. Mr. M. P. Merciles, representing the Fourth District Citizen's Association, urged the necessity of a new water-supply on the grounds that the present supply was both inadequate and impure, and contended that the city should keep the control of the supply. Drs. B. A. Watson and A. A. Lutkins also spoke in favor of a new source of supply. On the other hand a paper was produced in which sixty physicians of the city had certified that in all their practice, running back as far as forty years in the case of some of them, they had never been able to trace a case of illness to the city's water. The meeting finally adopted a resolution declaring that Jersey City should own and control its own water-supply, that it is against public policy to enter into any contract with any private corporation for a supply of water, and that a new supply is unnecessary.

— A death recently occurred in New York from chlorate of potassium. The victim was a laborer who worked in Central Park. Suffering from rheumatic pains, he sent his daughter to a druggists on First Avenue to procure some iodide of potassium for their relief. She either asked for "chlorate of potash" or the clerk so understood her, as he gave her the latter drug, and labelled the package to that effect. Without apparently examining the label, her father took half an ounce of the drug that evening, and the next morning another half ounce; and a few hours after the second dose he began to suffer from violent pains, which continued until death resulted.

— Dr. Benjamin Fradenburg, one of the oldest physicians in New York State, died at Palatin Bridge, at the age of ninety-one. He had practiced at Coeymans for over sixty years, and was well known all along the Hudson River.

Miscellany.

SULPHONAL.

THIS new hypnotic was discovered in its chemical relations by Bauman, and its action as a hypnotic by Professor Kast.

It is in colorless, tubular crystals, without odor or taste, melting at 130° to 131° C., and boiling at 300° C., beyond which temperature it decomposes. Medicinally, it has been found efficient as a hypnotic, giving quiet sleep, varying from five to eight hours, without producing any abnormal depression. The dose is about thirty grains, suspended in water, or given in wafer or capsule.

THE PHYSICS OF THE MALE URETHRA.

MR. W. W. WAGSTAFFE, in a paper in the St. Thomas Hospital reports, vol. xvi, noticed in the *London Medical Recorder*, July 20th, points out as the result of his observations that the urethra is rifled somewhat after the manner of a gun-barrel, but the spiral of the urethral tube which runs from right to left in about the upper three-fourths of its length usually becomes reversed near its distal extremity. The object of the spiral grooving in the case of the gun is to secure for the projectile a rotary motion and greater precision in direction of aim, and we may fairly assume that similar advantages of a physiological nature are gained for the outflow of the urine and semen by the arrangement of the urethral column. It is some-

times stated, he notes, that a twisted stream is one of the early signs of stricture, but this is misleading, since the normal outflow is always perceptibly spiral. This phenomenon is perhaps not altogether due to the urethral rifling. since it has been found that water forced out of a narrow, smooth-edged slit does not continue in a straight "tape" jet, but is shot out as a spiral.

TETANUS TRANSMITTED BY INOCULATION.

The Austrian correspondent of the *British Medical Journal* says that at a recent meeting of the Imperial Royal Society of Physicians, of Vienna, Dr. v. Eiselsberg gave an account of a case of tetanus, which had been in the clinic of Professor Billroth. A woman aged forty, drove a splinter of wood into the palm of her hand whilst scrubbing the floor. A fragment of the splinter was extracted by her husband. During the course of the next week, an abscess formed in the hand; this was opened by the attending physician. On the twelfth day after the injury, the woman was admitted into Professor Billroth's clinic with the typical symptoms of severe tetanus, which lasted four weeks. She afterwards recovered to a great extent, and was discharged at her own request. At that time she still presented slight contractions of the affected limb. Two months later, a suppurating fistula was formed, and a small splinter of wood came away in the discharge. The wound then completely healed, and the patient made a perfect recovery. Dr. v. Eiselsberg used the extracted piece of wood for preparing cultures. Two rabbits were inoculated with the culture thus obtained, one of which succumbed to tetanus on the sixth day after inoculation, while the second one, which was inoculated at a later date, showed marked symptoms of tetanus, such as increased irritability, trismus, pleuro-thotonus, etc. Dr. v. Eiselsberg showed this rabbit to the Society, and foretold that it would also die in a few days. The lecturer formally called attention to the fact the pathogenic bacillus of this disease was also to be found in the garden mould and the gravel. He will next report on a number of other experiments on the etiology of tetanus.

GROUPED CELLS IN ASCITIC FLUID AS DIAGNOSTIC OF MALIGNANT DISEASE OF THE PERITONÆUM.

Dr. H. C. Coe demonstrated at a recent session of the New York Clinical Society, as reported in the *New York Medical Journal*, the presence of the sprouting cell-groups of Foulis in a drop of ascitic fluid withdrawn the day previous from the abdomen of a patient with undoubted secondary cancer of the peritonæum, who had been under observation for some time at the Cancer Hospital. His attention had been directed to these cells by Dr. Welch seven years before, and since then he had sought for them in every specimen of ascitic fluid submitted to him. Although he had found them but once in cases of cancer of the liver, even where the omentum had been affected, he could recall several cases in which the presence of numerous cell-groups had led him to diagnosticate malignant disease of the ovaries and peritonæum, and in which diagnosis had been fully confirmed by a subsequent exploratory incision or autopsy. He thought that every pathologist who had given this question careful consideration must disagree with Tait, who, in the last edition of his work on "Diseases of the Ovaries," had said that he placed no reliance on the presence or absence of these cells in fluid removed by tapping. At the same time that author was correct in affirming that these elements were not always found. The speaker believed that, when they were found in the free fluid they denoted the presence of an exuberant malignant growth, either carcinoma or sarcoma; they might also indicate the outgrowth of papillomatous material through the wall of an ovarian cyst, with extension of the disease to the peritonæum. He had always deprecated a resort to exploratory incision in cases in which advanced malignant disease was strongly suspected, since, so far as his own observation extended, little additional information was gained, and the patient frequently either succumbed to the shock of the operation, or. if she recovered from it, grew rapidly worse. He thought that a careful examination of the fluid withdrawn with an aspirating needle would often render the diagnosis so clear that the patient would be spared such operative interference.

CAN THE FŒTUS *IN UTERO* BE INFECTED BY THE MOTHER?

The special Berlin correspondence of the *British Medical Journal* for July 14th contains an abstract of a paper by Prof. Max Wolff in Virchow's *Archiv* on the much-debated question whether micro-parasites can possibly pass out of the maternal into the fœtal blood through the placenta. He began his experiments with the anthrax bacillus and vaccine matter in pregnant animals. Wolff rejects mere clinical observations in such matters as uncertain, and liable to all kinds of fallacies. Only experiments in which one is able to infect the animal, either before or after conception has taken place, are of any value; by killing the mothers, one is able to interrupt the process at any time and to examine the fœtus *in utero*, so that there can be no doubt about an exact bacteriological proof of inheritance. According to former opinions (Bruell, 1858; Davaine, 1867; Bollinger and Koch, 1875), the anthrax bacilli are never transmitted from the mother to the fœtus. But, according to more recent work done in Pasteur's laboratory (Koubassoff, Straus, Chamberland), micro-organisms may very easily pass through the placenta into the fœtus. Wolff has worked out this question experimentally with the most minute and laborious precautions, using in every case the three branches of the bacteriological method; namely, microscopic examination of organs, cultivation of bacteria, and inoculation. The result of the first method was entirely negative in 29 animals. Of 156 cultures, 150 remained sterile, while six gave a positive result. Of 29 animals inoculated, 26 remained well. Where anthrax was found in the fœtus, two of these methods always gave results, and only one in favor of infection of the fœtus by the maternal blood. For this reason, Wolff concludes that the separating wall of the placenta is not pervious by the anthrax bacillus, and attributes to defects in the technical process the few cases which occur to prove the contrary. Of course, he does not deny that it is possible for bacilli to migrate through the placenta into the fœtus, but only under pathological conditions, in cases of hæmorrhage in the placenta, fœtal inflammations, convulsions, etc. Wolff also

maintains that the vaccine contagium cannot pass through the placenta. Of twenty pregnant women, twelve were vaccinated with success, and their seventeen children were vaccinated on the first to the sixth day after birth. In every case well-defined pustules appeared, showing that the children were not in a state of immunity. It is now fully ascertained that the children, while yet in their mother's womb, may contract genuine variola if their mother suffers from small-pox during pregnancy. Wolff, in admitting this fact, points out its rare occurrence, and explains it by the tendency to hæmorrhage so frequent in patients suffering from small-pox; in such pathological conditions, as has been said above, the blood may pass from the mother to the fœtus through the placenta.

A CASE OF PERFORATING WOUND OF THE ABDOMEN INFLICTED BY AN OX'S HORN.

The *London Medical Recorder*, July 20, contains the report of a remarkable case of abdominal injury reported by Dr. Nikolar S. Gratch in a Russian medical journal (Med. Obozr, No. 2, 1888).

The case was of a weak and emaciated peasant woman, aged fifty-five, who, when waiting on a village road for a herd returning home, was suddenly attacked by an ox, which threw her up in the air, caught her on one of his horns, and then tossed her about on the road for several moments before aid could arrive. The woman got up by herself, and was even able to walk home, "feeling all the way that something warm and moist was dangling between her thighs," but, on reaching her staircase, she became so faint that it was found necessary to carry her up and to send at once for a clergyman and for the writer. When seen by the latter, seven hours later, the woman lay on a dirty palliasse on the dirty floor of her hut. She was in a state of collapse, had a weak, uncountable pulse, pinched face, and scarcely audible voice, and complained of epigastric pain. Her chemise having been divided with scissors, a "large mass of distended, partially quite dry, intestinal loops presented itself, covered with another soiled and blood-spotted chemise." The prolapsed mass being pushed aside, an extensive triangular flap consisting of the abdominal integuments alone was found, with its apex about two centimètres from the pubes, while its sides ascended from this point obliquely across the inguinal regions to terminate somewhere on the line dividing them from the corresponding infra-umbilical lines. The abdominal wall was perforated through all its thickness, only about the left angle of the triangle. There were, besides, some superficial bruises about the thighs. Having administered twenty-five drops of simple tincture of opium (Ph. Russ.) in two doses, Dr. Gratch washed out the protruded mass (which seemingly included a portion of colon) with a tepid solution of corrosive sublimate (1 to 5,000), then carefully examined the parts in regard to their integrity, and returned them, without any special trouble, into the abdominal cavity, closing the perforation with several superficial and deep sutures, and applying an iodoform dressing. The after-treatment consisted only in the internal use of the opium tincture (five drops four times a day), cold milk diet, and strict rest in a supine position. Recovery proceeded so satisfactorily that on the fourth day she could be safely removed to the town hospital. The temperature never rose above 38° C., and became normal on the seventh day, about which time also regular action of the bowels was established. On the eleventh day all sutures were removed. When seen about six weeks after the accident the patient was quite well, but was obliged to wear a supporting abdominal bandage since, otherwise "she felt some peculiar weight in the hypogastric region when walking." Dr. Gratch is not very sure whether his patient's recovery from her severe injuries could be attributed solely to the antiseptic precautions adopted, since the woman's surroundings up to her removal to the infirmary were quite the reverse of hygienic, and all his cleansing and disinfecting manipulations could only be carried out on a dirty floor and in semi-darkness, contributed by a dwarf petroleum lamp and a tallow candle. In common with other Russian country practitioners, Dr. Gratch thinks, generally, that "rustic dirt is not so dangerous as the doubtful cleanliness of infirmaries," and that hence "bad hygienic conditions of villages must not be regarded by the surgeon as an obstacle to surgical operations."

A VISIT TO THE CLINIQUE OF DR. APOSTOLI, OF PARIS.

We make the following extract from a Paris letter from W. Macfie Campbell, M.D., to the *Medical Press*, describing the technique of Dr. Apostoli in the electrical treatment of fibroids.

We will now suppose that an old case of fibroid is on the table. The case-book shows that she has had the galvanic puncture five or six times, and under treatment perhaps six months. The menorrhagia is quite under control, she is still blanched-looking, but bright, and says she is now able, and has been since the first month for her usual work as charwoman. Only the galvano caustic is to be used to-day. She is placed on her back with the thighs separated, the surgeon himself irrigates the vagina with 1-1000 sublimate solution, passes the sound, which has been burnt over a spirit lamp, then dipped into the sublimate solution, and anointed with carbolic vaseline. The clay electrode is placed over the abdomen, any abrasion of skin being covered with a piece of moistened paper, and the connection made. The current (probably negative) is generally increased to 20, 30, 70, 150, or even 200 milliampères, according to the former toleration of the patient and her present capability of bearing increase. The current is continued for five to eight minutes, and is sometimes accompanied by hæmorrhage, then the vagina is again irrigated, and a tampon of iodoform lint is inserted through a speculum (this for two reasons — as an antiseptic dressing, and as a preventive for coition), and the patient is sent to her seat for an hour or two. They walk or drive home, sometimes long distances, and are able for their work next day.

With our next case puncture is to be employed — the same irrigation is carried out — and Dr. Apostoli (after washing his hands carefully in the mercurial solution) makes a bimanual examination, and determines the place of his puncture, choosing the cul-de-sac or the posterior lateral aspect of the tumor, fixing his finger on the chosen spot (which must not be near any pulsating area) he passes the loose canula along his finger to the place, then having determined the depth

of his puncture by the trocar's movable handle, he presses it on, making a puncture of one-third to three-quarters of an inch in depth. A shorter period and fewer milliampères are employed, and the pain is evidently greater. In his private practice chloroform is sometimes needed. The case is then irrigated and dressed as before, and told to appear in two days. Thereafter, until the slough separates, a matter of eight days, she is instructed to use hot water sublimate irrigation (1–2000 to 1–3000) four or six times daily. This case may require one puncture a month for several months with the galvanic caustic between, but the patient, with two days' rest after the puncture, is able for all her work, and seems more than content to go on with her treatment.

For chronic endometritis and active hæmorrhage the positive pole is used, and the electrode carried to all parts of the cavity, so as to act upon the entire uterine mucous membrane.

For acute endometritis, peri- and parametritis, a long previous course of irrigation with hot water is enjoined, and no operative interference is attempted until pain to the touch is gone, or the sound can be passed almost painlessly.

For acute para- and perimetritis nothing is done while pain and tenderness remain, but when the painless or chronic stage is reached, the puncture is made into the most accessible part of the hyperplastic exudation, and the treatment carried out as before. A case like this may need ten punctures, and the galvano-caustic simple has but little effect upon it.

Dr. Apostoli's apparatus consists of a Leclanché or bisulphate of mercury battery of thirty-six cells of a rheophore of clay for the abdomen, of sounds of platinum for the galvano caustic, of trocars of steel for the puncture, with their canulas, and of the bi-polar insulated sound for use with the interrupted coil machine. In his private house he also provides what he calls an electric bath of static electricity, by a large friction machine worked by an air engine. This apparatus is capable of giving a spark of six inches, and not worked at its full strength, is used in directing the fluid to any required portion of the patient's body, being provided with suitable conductors. I saw myself, with this machine, a spark of one and one-half inches drawn from a woman's arm without the appearance of much pain, while the current formed was strong enough to make the bystanders' hair stand on end literally at a distance of one or two feet.

The distinguished feature of Dr. Apostoli's machinery is the galvanometer by which he is enabled to measure the strength of his constant current up to 200–300 milliampères, and the strong point of his conduct of a case is his strict attention to antiseptic details. In no case did I notice the smallest departure from the rules he has laid down for the strictest antiseptic cleanliness of his instruments and hands, a cleanliness which he insisted upon also in his visitors.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 1, 1888.

Deaths reported 2,656: under five years of age 1,246; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 827, consumption 283, acute lung diseases 139, diarrhœal diseases 517, diphtheria and croup 90, typhoid fever 86, whooping-cough 38, scarlet fever 34, malarial fever 36, measles 19, cerebro-spinal meningitis three, erysipelas two, small-pox two. From whooping-cough, New York 17, Brooklyn six, Philadelphia four, Baltimore, Boston and Pittsburgh three each, Cincinnati and New Orleans one each. From malarial fevers, New Orleans 14, Brooklyn six, New York and Baltimore five each, Philadelphia three, Charleston two, Boston one. From scarlet fever, New York 25, Brooklyn four, Philadelphia and Pittsburgh two each, Fall River one. From measles, New York 16, Brooklyn, Pittsburgh and Fall River one each. From cerebro-spinal meningitis, New York, Philadelphia and Baltimore one each. From erysipelas, Boston two. From small-pox, New York and Philadelphia one each.

The meteorological record for the week ending September 1, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending Saturday, Sept. 1, 1888.	Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. A., FROM SEPTEMBER 1, 1888, TO SEPTEMBER 7, 1888

WORTHINGTON, J. C., captain and assistant surgeon. Ordered from Fort Crawford, Colo., to Fort Townsend, W. T. S. O. 206, A. G. O., September 5, 1888.

HALL, J. D., captain and assistant surgeon. Ordered from Fort Townsend, W. T., to Fort Niagara, N. Y. S. O. 206, A. G. O., September 5, 1888.

BROWN, P. R., captain and assistant surgeon. Ordered from Fort Niagara, N. Y., to Fort Sidney, Neb. S. O. 206, A. G. O., September 5, 1888.

ALLEN, CHARLES H., major and surgeon, STERNBERG, GEORGE M., major and surgeon; MCELDERY, HENRY, major and surgeon; and CARTER, EDWARD C., captain and assistant surgeon, are a board of medical officers which is constituted to meet in New York City on October 1, 1888, or as soon thereafter as practicable, for the examination of assistant surgeons for promotion, and of candidates for admission to the medical corps of the Army. S. O. 203, A. G. O., September 1, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING SEPTEMBER 10, 1888.

PURVIANCE, GEORGE, surgeon. To proceed to Fairport, O., as inspector. August 27, 1888.

MURRAY, R. D., surgeon. To proceed to Key West, Fla. September 5, 1888.

HUTTON, W. H. H., surgeon. To take temporary command of Camp Perry, Fla. September 8, 1888.

GUITERAS, JOHN, passed assistant surgeon. To proceed to Jacksonville, Fla., after return, from duty, on special train from Jacksonville to Hendersonville, N. C. September 8, 1888.

WASDIN, EUGENE, passed assistant surgeon. To rejoin his station at Mobile, Ala. September 5, 1888.

BRATTON, W. D., passed assistant surgeon. To proceed to San Francisco, Cal., and report to surgeon H. W. Sawtelle, for duty. September 8, 1888.

MAGRUDER, G. M., assistant surgeon. To proceed to Mobile, Ala., and assume temporary charge of the Service. August 31, 1888.

FATTIC, J. B., assistant surgeon. To proceed to Memphis, Tenn., and relieve passed assistant surgeon C. T. Peckham. August 31, 1888.

MAGRUDER, G. M., assistant surgeon. To proceed to Way Cross, Ga. September 6, 1888.

DEATH.

Died in Lowell, Mass., September 9, 1888, John Cochrane, M.D., M.M.S.S., aged forty years.

BOOKS AND PAMPHLETS RECEIVED.

Annual Announcement of the New York Polyclinic and Hospital. A Clinical School for Graduates in Medicine and Surgery. Session of 1888–89.

Obstetrical Antisepsis. By Dr. Auvard, editor of "Archives de Tocologie," Accoucheur des Hôpitaux, Paris. Reprint. 1888.

Transactions of the Medical Association of the State of Missouri, at its Thirty-first Annual Session, held at Kansas City, Mo., April 17, 1888.

Réfutation des Recherches sur la Fièvre Jaune faites par Mr. P. Gibier à la Havane, par le Dr. Domingos Freire, Professeur de chimie organique et biologique à la Faculté de Médecine de Rio Janeiro, etc. 1888.

Excessive Venery, Masturbation and Continence; the Etiology, Pathology and Treatment of the Diseases resulting from Venereal Excesses, Masturbation and Continence. By Joseph W. Howe, M.D., author of "Emergencies" etc. N. Y. E. B. Treat. 1888.

Addresses.

ON MEDICAL MUSEUMS, WITH SPECIAL REFERENCE TO THE ARMY MEDICAL MUSEUM AT WASHINGTON.[1]

BY JOHN S. BILLINGS, M.D., *Surgeon, United States Army.*

GENTLEMEN of the Congress: Our articles of confederation require that the President shall give an address. In endeavoring to comply with this regulation, I must ask your indulgence, for, while I think I have something to say, I cannot give you such a discourse as would befit the audience, the occasion, and the subject.

The prominent characteristic of the great majority of the societies composing this Congress is that their members have, as a rule, been chosen because they have either made some valuable contributions to medical literature, or have, in some way, rendered aid to the profession; in other words, they are supposed to be men whose labor and thought have not been confined to their own interests, or to those of their own patients. It may, therefore, be assumed that you are all interested in medical science, not merely as a means of giving new modes of diagnosis or of treatment, but also for its own sake, for the sake of knowing, for the pleasure of investigation, and in the hope of helping others, and that, while the majority have devoted themselves more or less to special branches, they have not, in so doing, lost interest in what may be for the general good of the whole profession.

I am here as the representative of the medical departments of the general government, which has need of the best knowledge of all the specialties, and is beginning, in its turn, to do something for each.

The physicians in the government service are all general practitioners, and are expected to have such an education and training as will fit them to deal, alone and without consultation, with the diseases and injuries to which men, women, and children are liable. You have been, and still are, their teachers — in the lecture-room and the hospital before they entered the service — in your text-books, monographs, and contributions to journals or transactions which follow them to their widely scattered posts of duty. They are your warm friends; the more you discover, the greater your skill, the more recognition which your work receives, the better they are pleased.

Within the last twenty-five years the general government has, in its turn, done something for medicine and for you by founding and maintaining a medical library and museum in Washington under the direction of the Medical Department of the Army.

I have had occasion several times to call attention to the library, which, no doubt, is that part most immediately useful to physicians, and which has attracted most attention. To-night I propose to speak of the other branch, in whose proper development it is desirable that you should take an intelligent interest, and, after giving a brief sketch of the development of modern medical museums, we will consider more especially our own national medical collection as it is and as it ought to be.[2]

The origin of collections of objects of natural history was possibly, as suggested by Beekman, the custom of keeping curious objects in temples; but we have no record of the formation of any collections specially connected with anatomy or medicine before the sixteenth century. It is true that human anatomy had been introduced in the schools by Mundius in 1306, and that, no doubt, in Bologna, in Paris, and a few other places, a skeleton or two was preserved for purposes of instruction; but alcohol was unknown as a preservative before the end of the fifteenth century, anatomical details were of no interest until Vesalius had stirred up controversy with the Galenists, and injected preparations were not thought of until after Harvey's announcement, in 1628, of the discovery of the circulation of the blood.[3]

The introduction of the use of the microscope at the beginning of the seventeenth century, and the collections of preparations for use with this instrument made by Leeuwenhoek and Ruysch, gave a powerful stimulus to formation of museums of this kind. The most famous of these collections was that of Ruysch, purchased in 1717 by Peter the Great, and sent to St. Petersburg. Ruysch was practically the first to prepare injected anatomical specimens for permanent preservation, and, if the stories told of his work are true, he made preparations which have never been surpassed. His museum was a very ornamental one, the bones and skeletons being arranged in various devices, the plants in bouquets, while scattered through the whole were beautifully engrossed sentences from the Latin poets.

The most famous medical museum in the latter half of the eighteenth century was that founded by Fontana at Florence. This still exists, filling a series of rooms, and consists mainly of wax preparations, beautiful to look at, but inaccurate and of little scientific value.[4]

During the first half of the present century a number of private collections were formed by anatomists, pathologists, and surgeons. Most of these have become public collections, either by gift or purchase, and the rest have been dispersed or destroyed. There is not in existence at the present time any large collection of specimens pertaining to human pathology which is the property of an individual and is at all comparable to those made by John or William Hunter, Astley Cooper, Howship, Liston, or others, unless it

[1] The President's Address, delivered September 20, 1888, before the Congress of American Physicians and Surgeons, Washington, D. C.

[2] As a "museum," in the original sense of the word, is a building or place in which are collected objects of interest to the muses — that is, objects of art, literature, etc. — the phrases "medical museum," "museum of pathology," etc., would have seemed quite improper in the days of Hippocrates, just as the prevailing pronunciation of the word múseum grates on the ears of the elders accustomed to the strictly proper way; that is, museum. Custom has, however, so strongly sanctioned the use of the word museum in the sense of a collection of different articles, that it would be folly to attempt to give it a more limited signification, and, though lexicographers still recognize only the word as accented on the penultimate syllable, the tendency to accent the first syllable is so strong and constant that it is safe to predict that múseum will, in popular usage in this country, ultimately win the day.

[3] For accounts of the collections formed between the days of King Solomon and the end of the seventeenth century, consult tome ii of the Musei Museorum of Michael Bernard Valentin, in folio, published in Franckfort in 1714, wherein are curious engravings of many of the wonders contained in these museums. See, also, Hagen (H. A.), "The History of the Origin and Development of Museums." American Naturalist, 1876, x, p. 80.

[4] The first use of wax models to represent pathological specimens or dissected preparations of parts of the human body is attributed to a Sicilian priest, Gaetan Jules Zambo, who lived in the latter part of the seventeenth century, and who had been accustomed to make wax models of diseased or deformed hands, feet, etc., to be used as *ex voto* offerings at the shrines of certain saints. The fame of these induced a Florentine surgeon, Ricci, to visit the priest and to get him to model some pathological specimens which he furnished. A Franciscan, named Desrones, brought this art to France, and made many such models between the years 1703-1706, and Bianchi formed a large collection of the same kind in Italy. It was scattered after his death, and the last vestiges of it were two models representing a healthy and diseased liver, which were to be seen in Innspruck in 1766. (Percy et Laurent in Dict. des Sci. Méd., Paris, 1818, vol. xxxv, article "Museum.")

be that of the Mott Museum in New York. Commenting on this fact, Sir James Paget writes me that he does not know of any large private pathological collection, and that he believes the change to be entirely for the better.

The necessities of modern progress in anatomy, physiology, and pathology have led to the creation of medical museums in all parts of the civilized world. In most of the continental capitals these are connected with universities supported by the State. In Great Britain and in this country they are, as a rule, connected with private or semi-private institutions for medical teaching. This difference is connected with the relative position which medicine holds in the educational machinery of the State in different countries. Where medical education is furnished by institutions directly supported by the government, the museums, which are a part of the apparatus required, are, of course, also supported by the government.

Through the aid of friends, whose kindness in replying or in obtaining replies to somewhat troublesome inquiries I cannot sufficiently acknowledge, I have obtained certain data with regard to some of the most important medical museums now existing in the world, and a part of these data are summarized in the table before you. Evidently, the city having the most valuable aggregate of anatomical and pathological specimens at the present time is London, which contains the collections of the Royal College of Surgeons, of St. Thomas's, Guy's, St. Bartholomew's, St. George's, and other hospitals, and of University College, the College of Physicians, and others. The oldest public anatomical museum in London is probably that of St. Bartholomew's, which, in 1726, had a room set apart for the purpose under the charge of John Freke, and which received the private collection of Abernethy. The most important medical museum in the world, and the one which has exercised the greatest influence in giving direction to anatomical and pathological studies, and in serving as a model for the formation of other collections, is undoubtedly that of the Royal College of Surgeons of London, the foundation of which was the collection made by John Hunter, purchased by the government in 1799. In one sense it is not a government institution, the funds from which it is now supported not coming directly from government grants; but in another sense it is truly such, since the College may be looked upon as an agent of the government having special charge of matters connected with medical education, as it is the principal examining body for those proposing to practise surgery in Great Britain.

The great value of the Hunterian collection lies in the breadth of its scope, which includes every branch of medical science; but it is preëminent in illustrations of human morphology and its abnormities. The museums of the great hospital medical Schools are relatively richer in the department of pathological anatomy, specimens of which they have greater facilities for obtaining. Among these there is, of course a certain amount of duplication of matters of interest; but no two pathological specimens are precisely alike, and the question discussed in the Paris school one hundred and fifty years ago; viz., "An pro distinctis ægris ægritudines diversæ?" is one that often occurs to a curator as he examines new specimens which differ but little from those already in this collection, but which do differ in some respects, and with regard to which he must decide as to whether, upon the whole, they are worth the trouble and cost of preservation.

Edinburgh and Dublin have also each large and valuable collections pertaining to anatomy and medicine.[5] In Paris the medical museums are those of the Faculty of Medicine, including the Musée Dupuytren devoted to pathological anatomy, and the Musée Orfila devoted to human and comparative anatomy, materia medica, natural history and instruments and apparatus.

Professor Leon Le Fort, to whom I am indebted for data with regard to these collections, remarks that a large proportion of the anatomical specimens of the Orfila museum come from candidates who take part in concours opened for positions connected with the anatomical teaching of the faculty — such as prosectors, demonstrators, etc., each candidate being required to furnish from ten to thirty specimens.

The medical museums of other European countries are connected as a rule with universities, and it is to be remembered that in these the different branches of medical instruction are each both more specialized and more comprehensive than is the rule with us. The professor of anatomy, of physiology, of pathology, has each his own building or institute, and, therefore, each his own museum; and unless this fact be held in view, comparisons between Continental and English, or American, medical collections may give very erroneous results.

With regard to the museums connected with American Medical Schools I will say little, referring you to the table and appended notes for such data as I have been able to collect. I am aware that in so doing I put aside a splendid opportunity to enlarge upon the general superiority of all these collections and the peculiar excellencies of each, but I think that you all know as much about these as I do, and there is time only for details with regard to the one American Museum in which I am specially interested. I will say only that the best museum connected with a medical school in this country is the Warren Museum in Boston, and that the history of the collections of wax models, upon which several of our museums have expended large sums of money, is very instructive as to how not to do it.

So far as mere number of specimens is concerned our own national medical collection is one of the eight largest in the world, and is increasing more rapidly than any other.

This collection, known as the Army and Navy Museum, owes its inception to Dr. Wm. A. Hammond, one of whose first acts after becoming Surgeon-General, in 1862, was to issue a circular stating that "as it is proposed to establish in Washington an Army Medical Museum, medical officers are directed diligently to collect and to forward so the office of the Surgeon-General, all specimens of morbid anatomy, surgical or medical, which may be regarded as valuable; together with projectiles and foreign bodies removed, and such other matters as may prove of interest in the study of military medicine or surgery."[6] By the end of the year

[5] I am indebted to Sir James Paget for the information given with regard to the greater number of the British museums. I had originally intended to attempt to obtain such data only from four or five of the largest; but on sending my little list of questions to Sir James he took such a kindly interest in the matter as to send a copy of these queries to a number of other museums with the request that they might be answered.

[6] Circular No. 2, Surgeon-General's Office, Washington, D. C., May 21, 1862.

over a thousand specimens had been collected, and the catalogue printed in 1866 showed that it contained 7716 specimens. It is not my purpose in this address to trace the history of its development; that must be done elsewhere. It has recently been placed, with the Library, in a conveniently arranged fire-proof building, and on the first of July last contained over 15,000 specimens besides those contained in its microscopical department, divided as follows:

Comparative Anatomy	1,689
Pathological	8,354
Medals	384
Microscopical specimens	10,416
Normal Human Anatomy	2,961
Instruments and Apparatus	814
Microscopes	141
Miscellaneous	835

Besides these there are 375 specimens pertaining to normal human anatomy and 726 to pathological anatomy, which are in what is called the provisional series.

It is not, however, by number of specimens that the importance and value of museums of this kind can be judged; and in this case such a comparison would give an exaggerated and erroneous idea of the value of this collection. My object in this address is not to boast of what we have, but to indicate what we want; to point out what a National Medical Museum, arranged to meet the wants and interests of this country, should be, should have, and should do, and to suggest some of the ways in which this is to be brought about.

At first the Army Medical Museum was limited to military medical subjects, but of late years its scope has been greatly broadened, and is now nearly the same as that of the Royal College of Surgeons. It includes human anatomy, physiology, pathology, somatological anthropology, instruments and apparatus, and illustrations of methods of teaching connected with special departments of practical medicine. It does not at present include hygiene or materia medica, except in their immediate relations to the military medical service, and this for reasons which will be stated presently. That our National Medical Museum should be broad and comprehensive in its scope there can be no doubt, its requirements in this respect being quite different from those of collections formed and used more especially for the purpose of teaching medical students. The most practically valuable of these last are those formed by individual professors to suit their own specialties and methods of teaching. They need not, as a rule, be large. I may even say that they should not be large; for the labor of properly preserving a large collection is great, and the student, with his limited time and want of knowledge of what to look for, can examine but few specimens so as to profit by them. For the same reason specimens of rare abnormalities, of double monstrosities, etc., are of little use in ordinary medical teaching as given in this country, and are not specially desirable in the museums of our medical schools.

You may have noticed that, in speaking of the scope of our museum, I said it included "human anatomy." This phrase does not mean that it has no specimens illustrating the structure of other animals — for it has many, and needs many more — but it means that in this department its main purpose is not to make comparative anatomy an end to itself by exhibiting all known variations in structure throughout the animal kingdom as a basis for their study in relation to development and environment, causation and results. In other words, it is not an anatomical museum, but a medical museum. The broad field of general biology, including natural history and comparative anatomy, will ultimately be covered by the National Museum, and in our medical collection it will be quite enough to illustrate human anatomy fully, using so much of the structure of the lower animals as will be useful in explaining why certain parts of the human body are thus, and so, and not otherwise. No sharp line of distinction can be drawn between the field of work of the general and that of the medical museum. So far as morphology is concerned, they must necessarily overlap somewhat, since both want a certain number of the same specimens, although using them to illustrate different points of view.

The medical museum should possess a series of specimens showing the normal anatomy of the domestic animals, or of animals used in experimental pathology, pharmacology, or physiology, as a basis for comparison with abnormal or pathological specimens derived from the same animals. It is in the section of embryology, illustrating laws of heredity and development, that specimens from the lower animals are most interesting, and this is especially the case in the study of human abnormalities and monstrosities. It is quite possible that to some anatomists it may seem that no limitation should be placed to the scope of the museum in this direction, for it is easy to trace some connection between any variation in structure in any animal and some structure, normal or abnormal, in man, but the limitation is placed, with reference to the work of the National Museum, so as to secure the best results.[7]

The kind of specimens most valued for illustrating anatomy in a museum is now very different from what was sought for in the first half of this century. Dried and varnished dissections, showing bloodvessels, etc., are now looked on as nearly useless, and are kept only as historical relics. Elaborate dissections under alcohol, mounted in opaque dishes, with flat glass covers, and sections of frozen bodies, similarly mounted, are what the student and the practitioner most desire to see. In our museum there are some excellent specimens of this kind, prepared under the direction of Professor His, of Leipzig; of Professor Cunningham, of Dublin; and by our own anatomist, Dr. Workman. These, however, are only samples to show how the work should be done. We require several hundred such specimens to illustrate properly regional anatomy in relation to age and sex, while the possible applications of the same methods to the illustration of visceral displacements, hernias, and deformities of all kinds are boundless. As regards physiology, but little can be done by museum specimens to illustrate function, as distinguished from form and structure. The so-called physiological series in the Hunterian collection is a series of organs illustrating variations in different families of the animal kingdom, or at different ages; in other words, it illustrates ontogenic and phylogenic development. The things students or teachers of physiology are most anxious to see in a museum are specimens of instruments and apparatus employed in experimental physiology, or in

[7] In the great majority of medical schools in this country anatomical teaching has a much more limited field than in the German universities, and our professors of anatomy, following English traditions, are usually in training for surgery. We have, however, several who are devoting their entire work to anatomy in the broad sense, and for its own sake, and it is in this direction that progress will be made.

the measurement of the special work of different organs, or in illustrating lectures on physiology. Illustration of results obtained in experimental pathology often belong quite as much to physiology; as, for example, specimens of results of Gudden's atrophy method.

The Army Medical Museum has only a beginning of such an anatomical collection as I have indicated as desirable. Like all other museums, it is richer in specimens illustrating osteology than in any other branch of anatomy, simply because such specimens are the easiest to obtain and preserve. We are accustomed to think that human anatomy is nearly exhausted as a field for original research, and that, at all events, every important organ or muscle or nerve has been figured, described, and named. Granting this, so far as the adult is concerned, although it is by no means true even for him, we have still to study the development of each of these organs or groups of organs, as seen at different ages, and, for some of them, in different races. As fast as these points are seen to be of practical interest, either in connection with diagnosis or the surgical treatment of disease, they are investigated; but an ideal museum should furnish the investigator the means for his researches; and it must, therefore, collect specimens without special regard to what is at present known to be their practical interest. The collection of such series of specimens of each joint, region, and organ, as I have in mind, including sections and dissections at different ages, from the earliest appearance in fœtal life to extreme old age in man, and in many cases in the lower animals, is a slow process. Such specimens, and especially such series of specimens, can only be prepared by a skilled anatomist, and there are few such; hence the formation of our ideal anatomical collection, limited though its scope may be, must be a work of time.

There is ample material and scope for original work for half a dozen skilled anatomists for many years to come to supply the demands of this museum for illustrations of human morphology in its various relations, and it is not desirable to scatter effort over too wide a field.

The pathological section of a medical museum is its main feature, being, as Mr. Flower remarks, the section to which, in the eyes of Hunter and his successors, all others form merely the introduction. It is true that to some physicians specimens in this department seem to have little value; but they are balanced by those physicians whose chief interest in a case of disease is to get a post-mortem. No doubt, much of the ancient pathology, and some of that which is quite recent, is comparable to the looking in the dark for a black spot which is not there, but those who despise pathology, and devote their entire attention to symptoms and treatment, err as much on one side as those who talk and act as if a knowledge of pathological anatomy could take the place of clinical experience do on the other. I do not know, however, that the doctrine usually preached, namely, that each man should attain the just mean in his views, is a true one. Certainly, it is not the principle on which the universe seems to be constructed; the balance is maintained, not by having everything exactly symmetrical, but by excess in one direction balancing excess in another.

To secure pathological specimens in their most instructive forms for museum purposes requires, in many cases, not only considerable variation from the usual routine methods of post-mortem examinations, but very considerable delay in ascertaining the results. If, for example, we wish the best specimens of the results of cerebral disease, the brain must not be removed and sliced up in the usual manner; it should be hardened *in situ* to a certain extent, and its sections should be carefully considered with reference to their preservation in their relations to each other before they are actualy made. There is need of a treatise by a skilled pathological anatomist, giving such methods in detail from the modern point of view.

Thus far the great majority of contributions of pathological material to our museum have been made by army medical officers: but some of the most valuable specimens have come from practitioners in civil life, and it is to these last that we must appeal for illustrations of the effects of disease in all parts of the country. There are difficulties in the way, of course. The physician in private practice does not make post-mortem examinations in five per cent. of the deaths of patients under his charge, and when he does come into possession of an interesting specimen he is very naturally inclined either to keep it himself, especially if it is an osteological one which can be preserved with little expense or trouble, or to put it in the little collection which has been formed at the dispensary, or asylum, or hospital. I hope, however, that when it becomes known that we are trying to form in Washington a complete medical museum for the benefit of the whole medical profession, and that we have the means of permanently and securely preserving, and exhibiting to the best advantage the specimens sent to us, I say that I hope and believe that when this is understood, many physicians will be willing to take a little trouble, and to give up something of their very natural impulse to keep a trophy of their skill, or a curiosity to talk about, in order to promote the general good.

As a rule, single specimens of abnormity or of disease have little scientific value; it is only when they are associated with others that they both furnish and receive light. To this audience it is unnecessary to give other reasons as to why physicians should contribute material to the national collection, nor as to why the curator of this collection is justified in being very bold in requesting such material; but there is one objection to parting with certain specimens which is sometimes made, and to which I will refer, as it brings up one of the ways in which our ideal medical museum can meet a practical need of the family practitioner. The objection I refer to is that the specimen may be important from the point of view of medical jurisprudence; that it has a special bearing in certain suits for malpractice, etc., and that, therefore, the owner wishes to keep it to be used as testimony to protect himself or his neighbors. There is some truth in this; but it is also true that such specimens brought together in the national museum would be just as available as ever for the protection of the rights of the individual physician, while they would also be available for the benefit of the whole community.

Whether the specimens preserved are, or are not, desirable for and useful to the museum, it is certain that the securing and forwarding them is a very useful thing to the physician who does it. It tends to keep him in touch with current living thought and work of the profession, to direct his attention to the connection

between symptoms and the mechanism of their production, which is often so important in deciding on the remedy to be used, and, above all, it gives him an interest in other men's work, and thus broadens his views and increases his knowledge and pleasure.

Having obtained the specimens, the next difficulty is so to prepare and preserve them that they shall be available for study. The great majority cannot be preserved in such a manner as to retain their natural color, size and texture. No doubt more might be done in this direction than is usually done. It is possible to stain or paint portions of specimens in such a way as to give some idea of the normal appearances, but thus far, I think, experience shows that the best medium for the permanent preservation of wet pathological specimens is alcohol, and this will contract and harden most tissues, and remove the color from nearly all. It is also an expensive mode of preservation for large collections, and requires constant care to prevent the effects of evaporation. It does not follow, however, that such specimens are of little value, and that, as some have urged, it would be better to seek to obtain records of the results of disease by colored drawings or models. The pathological specimen, whether seen at the post-mortem or years afterward in a museum, is to the scientific pathologist or the practical physician, merely a sign or hieroglyph of the morbid process which has produced it; it is a result, in most cases, of interest not in itself, but because of the preceding phenomena which it connotes. As Sir James Paget has said, the same objection, namely, that museum specimens are unfit for the teaching or the study of pathology, might be made to the study of botanical specimens in an herbarium. "In both cases alike the changes produced by preparation are so far uniform that any one accustomed to recent specimens (and no others should study either herbaria or pathological collections) can allow for them or 'discount' them. Just as an anatomist can discern, in a recent specimen of disease, the healthy structure; so, but often much more clearly, can the pathologist or any careful student discern in the prepared specimen the chief characteristic of the disease."[8] Colored drawings, casts and models are of great value in supplementing original specimens, but they cannot wholly replace them.

A good preparation, whether of normal or abnormal structure, but especially the latter, is valuable, not only for what we can see in it, but also for what we overlook or misinterpret, and which our successor may see, and see rightly. In this it is better than a mere description; yet the latter is equally necessary and much more easily preserved and made generally useful. Next to the preparation itself in accuracy and completeness of record is the photograph, and next to this is a good model, or a careful drawing.

In medical and surgical matters, as in most other things, we habitually think in terms of vision as interpreted by touch. Hence, in part, the importance of the so-called object-teaching, and the fact that what the medical lecturer shows his class will usually be much better remembered and understood than what he says to it. And while pictures and diagrams are of great assistance they are by no means as instructive and suggestive as representations in three dimensions, that is, models, if the thing itself is not available.

One of the most important sections of our museum is that devoted to microscopy, including normal and pathological histology and photomicrographic work. In the cabinets there are nearly 11,000 mounted specimens, illustrating almost every field of microscopical research. Many of these were made twenty years ago and more, and were mounted by processes which have not given good results, so that Dr. Gray, who is in charge of this section, estimates that about 3,000 will be set aside as worthless; but the rest form a very valuable series to which additions are being constantly made, and materials for which we are specially anxious to obtain. In connection with this section a series of cultures of chromogenic and pathogenic bacteria is kept up for museum exhibits, and also to illustrate methods of work.

While the great majority of the specimens in a medical museum have some relation to diagnosis, prognosis or therapeutics, the number of those which are of direct interest to the so-called practical physician is not very great. It includes models and casts illustrating dermatology, morbid growths, the results of amputations, excisions, plastic operations, etc., and instruments, apparatus, dressings, etc., of all kinds. Here also may be classed hospital fittings and furniture, means of transportation for sick and wounded, model cases of instruments, emergency chests, etc. Our medical museum has a fair beginning of a collection of this kind, including over a thousand specimens; but many more are needed to make it reasonably complete. If each medical man who devises a stethoscope, a pessary, a speculum, an ophthalmoscope, or an electro-therapeutic appliance with which he is well-pleased, would send a specimen to the collection, its increase would certainly be rapid, and it could always show the latest improvement.

An ideal medical museum should be very complete in the department of preventive medicine, or hygiene. It is a wide field, coveriag, as it does, air, water, food, clothing, habitation, geology, meteorology, occupations, etc., in their relations to the production or prevention of disease, and thus far has had little place in medical museums, being taken up as a specialty in the half dozen museums of hygiene which now exist.

Our own National Museum of Hygiene, is, as you know, under the direction of the Medical Department ot the Navy. It is a very interesting collection of sanitary appliances of various kinds; but it is not well-housed, is much overcrowded, and its location is so inconvenient that it receives but few visitors, and therefore, has by no means the educational influence that it ought to have. It should be provided with ample quarters in the immediate vicinity of the National and of the Army Medical Museums, to both of which it would form a very desirable supplement. In our medical museum, at present, military hygiene only is illustrated, and this only in a few branches, such as hospitals, means of transportation of wounded, etc. As regards materia medica, an exceedingly well arranged collection, including about 5,000 specimens, has been formed in the National Museum, mainly under the direction of Dr. J. M. Flint, of the United States Navy. The relations of materia medica to natural history, commerce, and the arts, which are subjects belonging especially to the National Museum, are as close as they are to medicine, and I am very glad that our national collection in this branch is where it is, and under its present management. In the Medical Museum we have a collection showing what is supplied in the way of drugs, instruments, etc., to the

[8] British Medical Journal, 1880, ii.

medical department of our army, and, as opportunity offers, we shall extend this to include the medical supplies of other armies or services.

The extent to, and manner in, which a medical museum should deal with anthropological and ethnological problems are not questions to be discussed in the abstract with advantage, since the answers must differ greatly according to circumstances. In our National Museums the matter has been so arranged that all material relating to anthropometry, or to real or supposed structural differences in man, according to race, are cared for in the Medical Museum, while specimens illustrating manners and customs, implements, weapons, clothing, pottery, etc., are taken charge of in the anthropological division of the National collection.

The Army Medical Museum contains what may seem a large amount of material relating to human osteology, and especially craniology, in its relations to North American ethnology, or the history of the development of different varieties of man on this continent; but it is not actually half large enough to permit of drawing definite scientific conclusions from it. The majority of the crania which it contains have been measured to a certain extent, and the results have been published; but many other measurements are desirable to permit of comparison with series taken elsewhere, and even measurements already made must be repeated by later and better methods. We have been trying some experiments with composite photography and superimposed contour tracings as a means of obtaining typical outlines and dimensions for race groups of crania, and these give promise of good results. If the collections of crania of North American Indians in Boston, New York, Philadelphia and Washington could be brought together, a very much better average presentation of the majority of tribes or groups would be obtained than can be furnished by either of these collections taken separately. By composite photography and tracings, combined with uniform methods of measurement, we can practically place these collections together, and obtain results nearly as satisfactory as if we had them all in one room. We have also fitted up one large room with instruments and apparatus for anthropometry in its widest sense, including psychophysical investigation, and it is intended to make this a complete laboratory for illustration of methods of work.

In London, arrangements have been made to have such an anthropometric laboratory in an out-building at the South Kensington Museum. The two things have no connection, and it seems to have been placed there because it would obtain more visitors desirous of being measured and tested than if placed anywhere else. In this laboratory, which is, I believe, essentially the same sort of institution as that arranged by Mr. Francis Galton at the Health Exhibition in 1884, and is planned by Mr. Galton; any person can have the regular series of measurements and tests made upon himself for a charge of six cents. There are difficulties in the way of making a charge for such measurements in a government establishment, and there are also difficulties in undertaking to do such work gratis, chiefly on account of the cost. It is, however, so desirable that it should be done, and the data which such observations systematically carried on for a series of years would be so valuable, not only from a scientific point of view, but for practical purposes in connection with life insurance interests, and very possibly with practical medicine, that we should endeavor to overcome these difficulties in some way, and I think it can be done sufficiently, at least, to stimulate private enterprise in this direction. It is possible that we may yet see in large cities establishments of this kind, directed by skilled and reputable physicians, having the confidence of the profession, where not only normal but abnormal conditions can be determined; places where the secretions can be tested chemically and microscopically, ophthalmoscopic and endoscopic examinations of all kinds made, the mode of functioning of muscles and nerves determined, and an authoritative record of the results made for the use of the individual, as evidence of his condition, or for the information of his physician. It would require an already established reputation and much skill and tact on the part of the director of such a laboratory, with absolute refusal to give prescriptions or advice in any shape, to make it fully successful; but it may be done.

An important feature of our national medical museum should be to show methods of research and of instruction for the benefit of the investigators and teachers of the country. This includes instruments and apparatus, and, to a limited extent, illustrations of the modes of using them and of the results; it also includes diagrams, models, etc., used for illustrating lectures. For example, as soon as Koch's researches became known in this country, physicians, and especially medical teachers who visited the museum, asked if we could show them the apparatus used by Koch and Pasteur in bacteriological work, and eagerly examined the few specimens of cultures on solid media which we were able to exhibit. The anatomist comes to the museum quite as much to see methods of mounting and preservation, as to see the specimens themselves; the physiologist does not expect to see function directly exhibited, but he does hope to find information about kymographs and constant temperature apparatus, and he wants to see whether Kühne's artificial eye is so useful for teaching purposes that he ought to get one to illustrate his lectures.

Medical museums are not, as a rule, freely open to the public, nor are they collected or arranged with reference to interesting or instructing non-professional persons. The Medical Museum at Washington is the chief exception to this rule, and it is so, because it was placed in Ford's Theatre, the scene of the assassination of President Lincoln. Many visitors to Washington, both men and women, wished to see this memorable spot, and in doing so, necessarily went through the Museum. This gradually led to the adjusting of the specimens exhibited with a view to the fact that they were to be seen by a number of non-professional persons of both sexes. Certain groups of specimens were put aside and not shown except to persons known to be physicians, while other groups were given prominent places because they interested the public, although not of great professional or scientific value.

On the other hand the public has gradually become accustomed to consider the Army Medical Museum as one of the "sights" of Washington to be visited by male and female, old and young, and when a stranger comes to the city and inquires what he ought to see, this museum will probably be named to him next after the National Museum. Since the collection has been moved into the new building near that devoted to the National

Museum, of which it may almost be said to form a part, the number of visitors has rather increased than diminished, and it has been found desirable to consider with care some problems which this state of things has forced on the attention of the curator. That educated men and women should have some curiosity as to the structure of their own bodies, the functions of certain organs, the arrangement of parts in certain localities where they have felt pain or discomfort, or the changes which have caused death in relatives or friends, is perfectly natural and proper, and there is no objection to gratifying this curiosity to a very considerable extent. The wonder to me is, not that boys and girls, youths and maidens, men and women, like to see specimens which will teach them something on these points, but that so many of them remain ignorant of, and careless about, the wonderful mechanism of their own bodies. Now what are the specimens in a medical museum which most interest the public, and in what direction is it expedient to try to direct this interest and to do educational work by means of the exhibits? In the first place, the majority of men and women, when at leisure and trying to amuse themselves, or to pass away time, prefer things that appeal more or less to the emotions, rather than those which appeal only to the intellectual faculties. The skeleton of a hand will be barely glanced at; but if it were known that it had been the hand of a great general, a great writer or a great criminal, it would be a specimen that almost every one who visits the museum would wish to see. Usually it is not expedient nor even possible, to furnish the personal data which would arouse this purely emotional interest.

When people come to the Army Medical Museum and ask where General Smith's brain, or Judge Brown's heart, or the Hon. Mr. Jones's larynx, or Guiteau's skeleton is, and are informed by the attendant that he does not know where it is, and is not even certain that it is in the collection, there are some expressions of disappointment, it is true; and sometimes the curator is appealed to as a last resource; but a few words of explanation as to what the main purpose of the museum is, and the suggestion that one would not like to have his or her father's skull displayed and labelled with his name, no matter how great or how infamous he may have been, is usually quite sufficient to satisfy the seeker.

This addition of interest to a specimen by calling attention to certain sentimental or historical associations connected with it, is not only proper but desirable, for all specimens not derived from the human body; but for these last, the rule should be to wait a hundred years before publicly labelling them with the names of the persons from whom they are derived.

For scientific and professional purposes we of course want a history of the specimen, which will, as far as possible, give the data connected with its peculiarities, and among these may be race, occupation, and even name, though the emotional element does not enter into it at all. If, for example, we had before us a specimen of cancer of the stomach, it might be of great interest, taken in connection with the symptoms, or in regard to the question as to whether pylorectomy or gastro-duodenostomy would have been justifiable; but from a scientific point of view it would add little to the value of the specimen to know that it was from the body of Napoleon and not from an unknown soldier.

To return to our question as to what interests the public. Of specimens illustrating the anatomy and physiology of man no doubt the most interesting to non-medical persons are those connected with reproduction. In the hall of the Army Medical Museum, which is open to the public, we do not place specimens illustrating specially the anatomy of the genital organs; but we do exhibit a series illustrating embryology, and especially the development and growth of the human embryo, and there is no case in the museum before which the average visitor will linger longer. The specimens are clearly labelled; a lady may go there alone, and, unnoticed, may at her leisure learn something about her own peculiar function, and the provisions for the life of the new organism; and I think she will hardly find the same facilities for this self-study anywhere else in the world. I do not mean by this that other museums may not have larger and more instructive collections of such specimens, but that they are not available for the information of modest, respectable, non-professional women.

In what has been said thus far, it is chiefly the utilitarian point of view that has been made use of; but this is by no means the whole matter. No art, and no branch of science should form the sole end and object of a well-balanced life, and there are objects in every large museum which are of great interest, though they appeal rather to the emotional than the intellectual faculties of the spectator. There are many specimens in the Army Medical Museum which I would rather see removed than to lose John Hunter's lancet, which has no scientific interest whatever. So also its collection of between three and four hundred medals and tokens relating to medical institutions or distinguished medical men, or commemorating outbreaks of pestilence or the victories of preventive medicine, is one which should be made complete and fully displayed, though it would not be easy to demonstrate its utility to any one unless he were interested in the history of the struggles and triumphs of the medical profession.

The objects of a medical museum are to preserve, to diffuse and to increase knowledge. Its conservative function is to form a permanent record of what has been demonstrated and to fix the meaning of terms. Even in my briet experience of thirty years the terminology of anatomy, physiology, pathology, chemistry, and of most of the specialties has greatly changed, and this not only by the addition of new terms, but by the dropping of old one. To get useful results from the older literature we must know the precise significance of the old words, and, in some cases, the best way to learn this is to examine the specimens prepared by those who used such terms in their descriptions. The specimens in our museum which came from the collections of Professor William Gibson and Dr. Frank Hastings Hamilton are especially valuable because they were the basis of practical teachings, and should be examined by any one criticizing these teachings.

A large proportion of the pathological specimens in this museum illustrate conditions which now rarely occur, forming a group which it is safe to predict will never be duplicated. It is not only that they were gathered during a great war, but that they illustrate the results obtained when antiseptic surgery, as now understood and practiced was unknown. Never again, I hope, will there be brought together such a collection of the effects of pyogenic microörganisms on gunshot wounds, especially of bone, as may be seen in its cases.

The museum also preserves, for future investigations, objects whose nature of relations are not understood at the time when they are received, and which occur so rarely that the means of studying them by comparison can only be obtained through such preservation.

Upon the function of a museum as a diffuser of knowledge;—as a means of education—it is needless to dwell. That it should also strive to increase knowledge is equally certain. This is to be effected by study and comparison of its materials. The results of such study and comparison of a part of the Army Medical Museum collection have appeared in the volumes of the *Medical and Surgical History of the War*. Another part will, I hope, soon be utilized in a study of its collection of human skeletons and crania which has been commenced by Dr. Matthews, of the Army. But a considerable part is as yet only in the stage of agglomeration, and our present business is to collect and preserve, leaving to the future its full utilization.

A medical museum is really used, for purposes of study, by very few persons; but through the teaching of those few its lessons are made known to the whole profession. American physicians in investigating a subject do not, as a rule, think of inquiring as to what museums can show with regard to it, simply because they have not had convenient access to large collections and are not accustomed to make use of them. Thirty years ago we were in much the same situation in respect to medical literature; but as the libraries have grown, desire for bibliographical research has grown also, and I think that in like manner when we have secured a comprehensive National Medical Museum it will not only be made use of, but will give a powerful stimulus to the formation and progress of other more special collections elsewhere.

What should be the relation of this central national collection to those formed in different parts of the country, either in connection with medical schools, or with museums of broader scope? Certainly they should help one another, and this can be done in many ways. I do not in the least object to a generous rivalry to do the best work, to have the most instructive and the most artistic preparations. That is a good thing. But I would say to the anatomist of a school, when you have made a preparation which is noteworthy, offer to make a copy for the national collection, where it will be seen by the anatomists of all schools and of all countries. To the pathologist of a medical school I would say, after you have secured type specimens of your own collection put aside other good specimens for the National Medical Museum, which will furnish you materials for the purpose.

On the other hand, the collections of the National Museum are available for study by any proper person, and its duplicates should be used to aid other museums which may be in special need of them.

In common with several of the largest and most important medical museums, more especially those of the Royal College of Surgeons and of the Faculty of Medicine of Paris, the Army Medical Museum has the advantage of being closely associated with a large medical library which is in the same building, and at present under the same direction. The increased utility and attractiveness which this gives to both library and museum is very decided.

It is true that in some other institutions similarly arranged there has been some grumbling as to the proportion of funds allowed to the museum and to the library respectively, the museum enthusiast claiming that the librarian would rather have one rare old pamphlet than half a dozen entirely new vertebrates, while the bibliophile is sure that the demand of the profession for access to a full supply of books and journals is much greater than that for access to specimens. I can only say, from my own experience, that one who has charge of a library only, will probably not hesitate to take museum funds, if he can get hold of them, to buy books; but that when one person is responsible for both he will endeavor to give each a fair share of the resources at his command.

If we had to choose between having a great national medical library and a great national medical museum, no doubt most of us would take the library, because it would be of more immediate use to us; but no such unpleasant alternative is forced on us. There is no reason why we should not have both, and we must have both.[9]

I have time for only a very condensed statement of the wants of our national Medical Museum. In the first place it needs the intelligent interest and friendship of the medical profession of this country. To a very considerable extent it has had this; were it otherwise it would not be what it is, nor where it is. But it needs more of it, and it can never have too much. Every medical man in this country should help a little and provide for the perpetuation of his name as that of a physician interested in the progress of the profession by sending at least one specimen to it. It is omnivorous in its demands for material, as will be seen by the circular which it has recently issued. But I will name as special wants, human embryos, especially those of a very early age, monstrosities and malformations of all kinds in man or in the lower animals; results of old injuries, such as fractures or dislocations, or of surgical operations, such as excisions, stumps, etc.; injuries and diseases of the eye, ear and nose; new growths of all kinds; diseases of the brain and spinal cord; and specimens illustrating the condition of bones, joints, brain, larynx and other organs in extreme old age.

In the second place it needs a regular supply of funds from the general government. To form and keep in proper condition such a medical museum as this should be is a more difficult and expensive matter than those not acquainted with such work would suppose, and the gifts of specimens from the profession must be supplemented by ample means for the preparation, preservation and proper display of these specimens, and also for the purchase of apparatus and typical specimens of foreign work, in order that the Museum may be always able to show the latest state of knowledge and the best ways of doing things.

The annual appropriation for the Museum at present is $5000. This is sufficient, except that the printing of the catalogue of which I shall speak presently, must be an extra charge; but the medical profession should see to it that the amount is not reduced in the rhythmic spasms of partial economy with which some of our statesmen are afflicted.

The third need of the museum is of a series of the right kind of descriptions of its specimens, given on

[9] "There are few things in relation to our science of which I am more sure than this, that every possible method of studying it should be by all possible means promoted." Sir James Paget, in Lancet, January 22, 1887, p. 159.

labels and in a catalogue. Unaided by such descriptions it has for each man that which he can see in it, and no more. One man will see nothing but an old piece of bone, a shapeless mass of tissue bleached by alcohol, a case of old dingy brass instruments. Another will see in the same things a rare joint atrophy, implying curious abnormal nerve influence; a leprous nodule, whose history, if we knew it, would reach back through the lazar-houses of the Middle Ages to the far east, and whose bacilli may be the lineal descendants of those that vexed Naaman the Syrian; a case of microscopes illustrating the development of that instrument, from the first rough iron tube of the spectacle-maker of Nuremburg to the delicate and complicated instrument through which we now peer curiously into that world that lies within the world of unassisted vision. By our labels and catalogues we must tell men what to see; but to do this we must first see ourselves. The aphorism that a first-class museum would consist of a series of satisfactory labels with specimens attached means a good deal. Something has been done in this direction, as you will see on inspection of the cases; but I often wonder what sort of labels a man who has spent years in investigating the normal and abnormal structure and relations of one organ would write for our specimen of that organ. Such help as this we need; kindly, truthful criticism, the pointing out of errors and of new points of view for this mass of material.

We also need a series of printed catalogues. One of these should be in the form of compact handbooks relating to particular sections of the collection, and intended partly for the use of visitors while in the museum and partly as a ready means of letting distant friends know what material it most needs in different departments. It should also print a complete illustrated catalogue of the whole collection for the use of the investigators and teachers of the profession. Congress has been requested to grant authority for the printing of such a catalogue by the Government Printer. The material for it is nearly ready, and it would make three volumes each the size of one of the volumes of *The Medical and Surgical History of the War of the Rebellion*.

The subject of museum organization and management, is one of those with regard to which it has been said that a man who is interested in it passes through three successive states of mind; namely, First, he thinks he knows almost all about it, except a few minor points of detail which he is going to look up. Second, he feels that he will never know anything about it. Third, he believes he knows a little and hopes by experience and study to know more.

The museum needs earnest and well-trained students to work up its collections so as to advance knowledge, and, at the same time, to display properly the specimens so as to make them most instructive. To all such students we shall endeavor to afford opportunities for this work. Precisely how this is to be effected is not yet clear, but here is abundance to be done, and there are quite a number of men coming on the stage who want to do such work for its own sake, because it gives them pleasure. Sooner or later we shall have half a dozen or more of specially trained men busy in the laboratories and work-rooms of the museum, each engaged on his own problems, and the whole for the common good.

The medical museum hints at matters which lie outside the scope of known physical and chemical laws. Physicians have not, as a rule, been very virulent theologians; their studies and their daily work tend to give them compensation of bias in this particular, and, therefore, in this age of transition in beliefs, it is not so true of them as of others, that "the old hopes have grown weak, the old fears dim, the old faiths numb." In our medical museum yonder may be found abundant illustrations of the results of physical and chemical actions and reactions upon what was once living matter, and was connected with centres of consciousness, of intellect, of emotions which imply something more than ordinary protoplasm or mere metabolism. It brings together strange company. The men who dwelt on the sides of the Andes in the old Aztec days, the men who built cities in the Gila Valley centuries before the days of Columbus, the Esquimaux, and the Indian of the plains, black and white, red and yellow, all sorts and conditions of men are represented in those bony caskets which once held their centres of life and thought; but now are reckoned only as so many crania in the Museum catalogue. The great majority of the pathological specimens imply either suffering or death, or both, of the individual from whence they came. Some of them are the results of intemperance, of lust, of folly and crime; but some are the results of unselfish sacrifice for the good of others, true flowers of blood and pain. A large group of them form one of the relics of an acute paroxysm of disease of a great nation. The old pensioner likes to keep the battered ball which crippled him, and so these relics have an interest beyond that which is purely professional. That the nation is not crippled by its loss, takes nothing from their interest, and the fact that we are physicians does not imply that we look upon them from a medical or scientific stand only. Those of the combatants who survive, are now better friends than ever, and the museum specimens, coming as they do from the sick and wounded of both armies, and contributed by both Union and Confederate surgeons, enforce the lesson of the unity of the profession and of its interests, as well as that of our country.

Our museum, like the library with which it is associated, includes all the specialties. No physician is so learned or skilful that he can find no instruction there, and no one is so ignorant that he cannot comprehend some of the lessons which it teaches. Taken together these institutions should contribute in no small degree to our national prestige, for which eminence in scientific work and teaching is an essential element, and if it be remembered that they are only twenty-five years old, and that during that period we have been making medical history at a tremendous rate, surely some incompleteness and crudeness may well be excused or overlooked.

Speaking in behalf of the army medical department and for the dead as well as for the living, who have been charged with this work, I can truly say that we have been very proud of our charge, and that we have done our best, each according to his capacity and opportunities to make the museum and library such as a great profession and a great nation have a right to demand.

— Benevolent old gentleman in the park, to nursery-maid with charges: "Are those children twins?" — "Oh no, sir." — "Dear me, what is the difference in their ages?" — "Six hours, sir."

THE RELATION OF SOCIAL LIFE TO SURGICAL DISEASE.[1]

BY D. HAYES AGNEW, M.D.

THERE is no tyranny more exacting or despotic than that exercised by the conventionalities which govern our living. All stages of life from infancy to old age are under its domination. It dictates the education, the manners, the walk, the dress, the forms of speech — in fine, the whole being. Beyond all contradiction, the behests of fashion are vastly more influential in governing public conduct than any arguments drawn from the teachings of structure and function. As a rule, when the conflict is between taste and reason, the victory will be on the side of taste. In nothing is this more forcibly displayed than in the apparel used to protect the body.

It is not an agreeable task to peer into the wardrobes or dressing-rooms of our fair country-women. I have no special taste for exploring museums or bazaar collections. Indeed, without a key to interpret the curious and ingenious mechanisms for clothing the form divine, such an explanation would be like an archæologist attempting Egyptology ignorant of cuneiform inscriptions. I have, however, some knowledge of human anatomy in its broadest sense, and when I look upon the masterpieces of the human form, whether in marble or on canvas, a Belvidere, Apollo, or a Venus de Medici, and contrast these with the dressed-out specimens of modern women, I am forced to admiration, not so much at the amazing ingenuity displayed in concealing the divinely appointed form, as at the plasticity and patient submission of mortal clay under the despotism of a conventional inquisition. Were these processes of mutilation and abnormality harmless, did the body consist of a mere mass of protoplasm, capable, under the application of certain stimuli, of assuming normally protean shapes, the subject might be passed over with the feelings of a naturalist, but this is not so. These violations of the laws of structure bring with them serious penal inflictions, which, did they terminate with the original offender, might be dismissed with a sentiment of pity, but projecting, as they do, their baneful consequences to successors, they become proper subjects for criticism.

Let me name a few examples as illustrative of my subject: For some time the profession has been speculating on the causation of nasal and post-nasal catarrh, with its accompanying auditory defects, the growing frequency of which cannot have escaped general observation. Doubtless no single agency will explain the presence among us of this unpleasant disease, yet there are facts connected with this affection which, to me, are very suggestive. I cannot recall an instance in which I have met with the disease among females belonging to the Society of Friends, Dunkards, or Menonites. If this, on more extended observation, proves to be true, may not the head-dress peculiar to these people be accepted in explanation of their exemption? The bonnet which at one time overshadowed the entire head, as all know, has been gradually shrinking in its dimensions, until it has become a mere shadow of its former self, and offers no protection whatever to the head. As a substitute, I would not insist upon the quaint head-gear of the Friend, though I believe that any modification which will protect this part of the body will lessen the tendency to catarrhal inflammation of the naso-pharyngeal mucous membrane.

Muscular Restraint. — A legion of physical imperfections arises from muscular restraint. Among these may be mentioned weak ankles, narrow or contracted chests, round shoulders, projecting scapulæ, and lateral curvature of the spine. The foolish concession to appearance and the unwise partiality of parents for enforced education, the demands of which bear no just proportion to the capacity of the infantile mind, constitute the initial or determining force of these physical imperfections. In many cases the weak ankles of children, characterized by eversion of the feet, thus allowing the superincumbent weight of the body to be transmitted to the latter inside of the proper centre of support, is largely chargeable to the miserable practice of placing on the little ones, long before they are able to walk, boots tightly laced up the limb some distance above the ankles. The confinement of the flexor and extensor muscles by this constriction prevents that free play of movement which reacts so favorably on all the elements of an articulation, and that, too, at a time when the growing forces are at full tide, so that when the time arrives for standing and walking the muscles are unequal to the firm support of the joint. The consequence of this feebleness is soon seen in the turning outwards of the feet, throwing the strain on the internal lateral ligaments, which, in turn, become elongated through growth, and thus the defect becomes established. But the evil does not terminate here. The calcaneo-cuboid and the astragalo-scaphoid ligaments losing the proper support of the tendon of the posterior tibial muscle under the abnormal tension, begin to yield, and to the deformity of eversion is added that of "flat-foot." That the above is not a mere hypothetical explanation of the ankle defects, I have many times verified by finding the threatening symptoms disappear after liberating the imprisoned muscles and subjecting the enfeebled parts to a judicious massage. Under no circumstances, as is too often the case, should instrumental apparatus be applied, unless in cases where, from neglect, the deformity is thoroughly established and is progressive.

Take another deformity, that of bow-leg. On the earliest signs of the unsightly curve, the limb is too often tramelled with irons and the growth of the muscles arrested, when it is well known that if manual force be systematically applied two or three times a day, the limbs will gradually assume their typical form.

Again, in further illustration of our general text, take as an example a child who, for one long or two short sessions for six days of the week, sits over the study-desk, compelled to assume a position in which, from the inclination of the body, the shoulders fall forward, the head being supported most probably on the elbows and hands. In such a posture, the great serrati and pectoralis major and minor muscles are in a state of relaxation, while the erector spinæ and trapezei muscles are in a state of tension. This change in the posture of the shoulders gives the scapulæ over, without antagonism or resistance, to the action of the rhomboidei and the levatores angulæ scapulæ muscles, which, acting conjointly, cause that projection of the lower angles of the shoulder-blades which the older anatomists termed "scapulæ alatæ."

[1] The President's address, delivered September 18, 1888, before the American Surgical Association, Washington, D. C.

To all this must be added the very important factor of four to six hours in the school-room and two hours, at least, of home preparation for the following day's recitations, during which time the respiratory functions, having been reduced to a minimum of activity, the muscles of the chest are comparatively passive, and aëration of the blood tardy. Certainly, no combination of conditions could be better devised for forming contracted chests and round shoulders. It is not long before the watchful eye of the mother detects the change in the figure of her child. She will probably discover this and take alarm, even when the pale face, the languid air, and the capricious appetite of the child cause no anxiety; and then comes the second act in the drama of physical deterioration; namely, a resort to shoulder-braces and stays in order to accomplish that which the muscles should be taught to do without restraint or incumbrance.

Lateral Curvatures. — While it is true that lateral curvatures of the spine depend upon causes both central and peripheral, yet in no small number the deformity is clearly attributable to influences of a social nature. The young column, by reason of the non-union of the epiphysis and diaphysis, and the supple character of the ligaments, is extremely flexible. Whatever, therefore, destroys the muscular equipose, however inconsiderable the force, if persistently repeated, changes the centre of gravity, and develops primary and compensating curves. For six months in the year, any fine morning, groups of young children may be seen plodding along our streets with a miniature library of books suspended from one shoulder. To the already preponderating scale of the balance add the additional factor, a probably badly arranged light, compelling these little *savants* to assume a lateral inclination of the body in order to obtain the necessary illumination of the subjects of the study, and you have all of the conditions necessary for perpetuating the lateral deformity. "Just as the twig is bent the tree's inclined." As in the case of round shoulders, so here, in order to prop up the falling column, instrumental contrivances are immediately called into requisition. The body is incased in a formidable coat of mail, to be followed by muscular atrophy and permanent distortion of one of the otherwise most beautiful pieces of mechanism in the human frame. It is true that in most educational institutions for the young provisions are made for physical culture, and these are in some measure antidotal to the evils complained of, but, in my judgment, do not at all compensate for that free unstudied romp in the open air, untrammelled by the hard and fast rules of calisthenics, so fascinating to the young child. Nor does the evil end here. While the forcing process which is to stimulate the mental powers far beyond the real capacity of the immature and growing brain to receive is in progress, another is inaugurated which is to qualify especially the female child to acquit herself with distinction when the time arrives for entering the great world of society, or, as Thomas Brown would style it, "for the frivolous work of polished idleness." The gait and carriage must be reduced to prescribed rules, the voice trained down to a drawl, or trained to move like a mountain torrent. The muscular apparatus of the face must be taught to express, not the spontaneous and natural outflow of feeling which wells up unbidden from the magic chamber of the heart, but rather to produce an effect; and so this work of transformation goes on until it culminates in the full-blown society girl. Is it any wonder that under such a scheme of education, conducted throughout by a studied disregard of both the physical and mental constitution, and exercising as it does such tremendous drafts on the nervous system, that the world is becoming filled with a class of flat-breasted, spindle-limbed young women, unfitted for the varied and responsible duties of womanhood, qualifications, too, which under a different regimen and directed into proper channels would exert a most potential influence on all the great social and moral problems of the age.

While thus plain spoken on the frivolous methods of living, I do not wish to be understood as being unfriendly to the highest cultivation of the mental and physical powers, if conducted on lines in harmony with the organization, nor to any technique which may conduce to personal grace or elegance of manners, so that the manly or womanly personality of the individual be not sacrificed to the Moloch of sentiment and sham. Indeed, indifference to these things is inexcusable in either man or woman as not only lessening their influence in the world, but in many respects disqualifying them for the highest discharge of the duties of modern life. Valuable as may be the unpolished diamond, yet it is only after the wheel of the lapidary has worn away the dull incrustations that its true brilliancy is revealed, and the gem is fitted to adorn the brow or the breast of beauty.

Bodily Constriction.—In the further discussion of my subject, I may next notice the evils of visceral displacement and pressure, consequent on abdominal constriction. Whatever may be said in regard to Greek and Roman life, the infinite care which these people displayed in developing and maintaining the very best type of the human form is worthy of admiration. The Ionic "chiton" spoken of by Attic writers, and so often represented in the bronzes of Herculaneum, while it would not exactly satisfy the modern idea of dress, was at least free from the charge of interfering with contour of the human figure. The painters and sculptors of those classic days were reverent students of nature. Their delineations were true to life. Their works furnish us with no hour-glass constructions of the human body. The constriction of the waist operates injuriously on both the supra and infra diaphragmatic organs. Any force acting on the base of the thorax, and preventing the expansion of its walls, concentrates the function of respiration; which should be general on the apices of the lungs, and hence, under these circumstances, the movements of breathing are for the most part confined to the summit of the chest. As the initial seat of tuberculosis is located at the upper part of the lungs, may not the inordinate work entailed on these parts by constriction have some part in hastening such deposits in the female where the predisposition exists? It is this forcing inwards of the costal border of the thorax which causes the groove on the anterior surface of the liver so familiar to anatomists. This pressure cannot fail to interfere with the descent of the diaphragm and with the functions of the gall bladder and duodenum, and exercises no small degree of influence in favoring the formation of biliary calculi, females being peculiarly prone to such concretions.

The extent to which the liver may be damaged by extreme constriction of the waist, is well illustrated by a case quite recently reported in the *British Medical*

Journal in which a considerable portion of the left lobe of the liver had been separated from the right, the two being connected only by a band of connective tissue, and which enabled the operator to remove the detached mass without difficulty. The evil effects of this constriction on the viscera of the abdomen and pelvis is most strikingly witnessed in the embarrassed portal circulation, in the different uterine displacements, elongation of ligaments, displaced ovaries, tubal inflammations, hemorrhoids, hernia and other morbid conditions which either prevent or disqualify the woman for the exercise of those functions of maternity, and which in addition, through reflex influences, entail a host of functional disorders reaching into every avenue of the body and invading both the mental and moral constitution of the victim. So prolific have these infirmities become that a new department of surgery has been organized for their special management. To what, if not to social causes, can these morbid changes of structure in the pelvic organs, especially of the uterus and its appendages, be attributed? Why should laceration of the cervix uteri be so common an accident? Labor is a natural process and ought not under ordinary circumstances be attended by lesion of uterine tissue. I can conceive of no agency more likely to induce that muscular degeneration which predisposes to this accident than the modes and methods of modern living especially among the inhabitants of great cities. In the expression "modern living," much is embraced. It includes culinary pharmacy, over-feeding and drinking, insufficient or injudicious exercise, improperly heated apartments and a disproportion between the hours of exercise and rest. Contrast if you will the muscles of the hardy, country house-wife, who bearing the cares and responsibilities of a dependent family bustles about the live-long day in and out of doors, eats with a relish her plain and simple fare, repairs at seasonable hours to bed, and sleeps the sleep of the beloved, undisturbed by dyspeptic night-mare, and rising with the golden dawn resumes the round of domestic toil with a clear head and supple limbs. I say contrast this type of a class with that of another, the woman born to luxury and ease whose capricious and exacting taste taxes the art of the professional caterer, who drags out the morning hours toying with some crazy piece of embroidery or trashy novel, lunches at one, rides out in the afternoon for an airing of two or three hours, returns to a dinner of five or six courses at seven, completes the evening at the opera, the theatre or the assembly, and coming home after midnight, crawls into bed weary and exhausted in body and mind, only to rise with the best hours of the morning gone, for another day of aimless routine life. Can it be doubted that in the first case, with a digestion unimpaired, with the products of textural change consumed by functional activity and eliminated through the proper emunctories, the woman should possess a vital resistance and a tone of tissue altogether superior to that of the other, whose habits of living must necessarily favor their faulty metamorphosis?

To these same agencies must be attributed that brood of nervous and hysterical evils, for the relief of which the gynæcologist, too often I fear invades the domain of womanhood, around which her whole sexual nature revolves, and which, save only in the direst extremity, should be sacred against all operative intrusion.

Late Marriages constitutes another social evil, the penal inflictions of which involves both sexes alike. Pride and luxury determine long engagements or deferred proposals. Marriage, it is believed, necessarily involves an establishment, a display, a retinue of servitors. The good old notion of two souls being united in wedlock for the purpose of being mutual helpmates, and patiently together working up from modest beginnings to affluence, seems to be entirely at varience with the modern idea of this relation. In the meantime the young man is betrayed into unlawful sources of gratification, alike destructive to moral and physical purity, the pollution of which incontinence is often subsequently communicated and perpetuated to wife and offspring. I would not dare to say how many cases of this nature have been entrusted to my professional confidence, though I doubt not my experience does not differ from that of many of my professional brethren whom I address. It is under such circumstances that many of those infective inflammations of the fallopian tubes as salpingitis and pyo-salpinx arise and which entail the most serious deterioration of health.

The Foot and the Shoe.— It may be thought by some persons that the subject of the foot and the shoe is not of sufficient dignity to appear in a public address. The Romans and the Greeks thought differently. The literature of both people is full of references to the shoe worn by both sexes. So important, indeed, are the feet to the well-being of the body, that whatever impairs their usefulness, either for support or locomotion, becomes a positive calamity. Nothing can be more unlike the human foot than the modern shoe. Let any one leave the impress of his or her foot in the wet sand of the sea-shore and then place alongside of the imprint of a fashionable shoe; that the two were ever intended for each other would scarcely strike a child of the forests. The North American Indian entertains juster notions about clothing this portion of his body than does the civilized denizen of New York or Philadelphia. Compare the moccasin with the shoe of the city belle. Compare the *σανδάλιον* or the *πέδιλον* of Pollux and of Aristophanes with the same, and we shall see that the savage and the polished Greek alike understood the value of sound feet in the race of life. It is the imperfect adaptation of the shoe to the foot which constitutes the fruitful source of tired ankles, corns, bunyons, overlapping of the toes and ingrowing nails. Some idea may be formed of the magnitude of the evil from the fact that of eight hundred patients under the care of a prominent chiropodist of Philadelphia, the great majority of the defects were entirely attributable to the high heels and the contracted toes of the shoes. Especially do these physical encumbrances arising from a blind submission to social laws, operate disadvantageously to our fair women at the beginning of the new dispensation requiring both muscles and brains, and when her friends propose to sweep away all the old traditions and claim for her the earth, with all its masculine employments.

Games and amusements which in themselves are proper and praiseworthy, too often become developed into a craze, working both moral and physical mischief. Professor Leuf, himself a professional in the national game of base ball, has described the pitcher's arm, a condition of over-taxed function, and one in which all the anatomical elements of the upper arm are involved. There is also the tennis arm and the

swollen supersensitive prostate of the bicyclist, both due to the abuse of popular amusements.

Defects of refraction or visual defects, constitute another class of affections fairly attributable in many instances, to social influences. The number of children which may be seen in our streets any day, wearing glasses, has become a matter of common observation. It is far from being probable that the most exquisite piece of mechanism, the human eye, came from the Divine Artificer, imperfect. Because eyes are young it does not follow that they are thereby better fitted to sustain prolonged use. Just the reverse is true, and it is high time that parents and educators began to recognize the fact. The power of the eyes for continued use like that of other organs of the body, is one of gradation. It moves in the general procession and strengthens with the advance in life until development has attained to its zenith. Not only so, but the eye being a part of the body, it must suffer or rejoice through the operation of general causes. A bone may have its normal curves changed, a tendon may slip from its appointed groove, or a bloodvessel be destroyed, and yet very little disability be realized; but the eye is made up of such extremely delicate structures and acts according to fixed physical laws, so that not the slightest alteration of a curve or the mobility or density of its media can occur, without great vitiation of function. To exact, therefore, long hours of study from children of a tender age, involves a degree of functional strain, altogether disproportionate to the structural resources of the organ, and by disturbing the orderly processes of nutrition, give rise to hypermetropia, asthenopia, astigmatism, and its companion headache. That the picture is not too highly colored or the causation overstrained, we have only to contrast the children born and reared in those portions of the country not too much dominated by the methods of modern civilization, and who rarely demand a resort to artificial aid to provide for abnormalities of vision. The only remedy for the evil where infantile scholarship is insisted upon, is the Kindergarten or object system, the most natural and effective plan of impressing the young mind.

Renal Disease.—Is there any reasonable explanation drawn from sources of a social nature for the great frequency of those renal disorders which come more particularly under the care of the surgeon as crystaline deposits and calculi? For maintaining the general health at the highest physiological standard, a proper quality of food and the proper disposal of tissue waste are essential conditions. Along with wealth and luxury come the abuses of the table. Americans are fast becoming a nation of dyspeptics. Our country is so rich in the products of every zone that nowhere else in the world can you find such a variety of foods, animal and vegetable. These foods, manipulated in a thousand ways by the subtle art of the professional cook, almost necessarily betray one into excess, and also create the desire for wines and other alcoholic beverages to aid the stomach in disposing of its plethoric supply. In great cities, which furnish relatively the largest number of cases of renal disease, affecting preëminently the mercantile and sedentary classes, we find just the conditions favorable to their development. The competitions of trade keep the merchant always at white heat. Time is golden, and the street car and other means of conveyances annihilate distance, and the ride is substituted for the needful walk. A hasty lunch at the most convenient restaurant satisfies the inner man until the business of the day is closed, when, weary and worn, he is driven to his home to partake of a course dinner, the balance of the evening to be spent on the lounge with the evening paper or the latest periodical. As for the literary man, the fascinations of the study and the library charm him away with their siren voices from the fields and the highways until bodily exercise grows distasteful and repugnant. In the meantime there has been no provision made for the waste or tissue metamorphoses of the body through that great agency, exercise. These accumulate in the blood, the internal eliminating organs of which the kidneys are chief, are overtaxed; and then follows the evils of malassimilation and of excretion in the form of urates and oxalates, often resulting in the formation of calculi.

In conclusion, may we ever hope for a time when the race will realize that these bodies which we wear, which God has so highly honored by his own incarnation, are sacred temples to be kept in harmony with recognized physical laws, and not to be made instruments of mere animal gratification.

CASES OF CEREBRAL TUMOR.[1]

BY S. G. WEBBER, M.D., ADAMS NERVINE ASYLUM.

The following cases illustrate the various phases of cerebral tumor. In two the general symptoms, preceding the more local, are such as usually accompany cerebral tumor. They are more frequently due to the remoter effects of the tumor, to pressure, to disturbance of circulation, to irritation and reflex influences. Headache is the most common of these general symptoms. It is rarely absent: but, as in two of the cases reported, it may not precede the more local symptoms. In the first case the pain in the head was excessive. It is often less severe than in this instance. Probably the locality and severity of the headache depends upon the situation of the tumor and the rapidity of its growth. We do not know if the pain is due to pressure upon the membranes through which the nerves pass, or upon inflammatory changes causing the cerebral substance itself to become sensitive. When the pain is not definitely localized in a small area, but is spread quite generally over one side or the whole of the head, and when it radiates to neighboring regions, as face and neck, it is probable that the tumor presses upon branches of the fifth nerve, which are found in the dura mater.

The growth of tumors causes a change in pressure, the irritation is greatest at another place, the circulation again is affected differently, therefore the headache varies, or may cease for a while.

Of sensory disturbances other than headache, there may be pains in the limbs, a sensation of numbness or of formication, an oversensitiveness to certain impressions, or to all impressions, upon the surface, or an increased acuteness of special senses. Sometimes the hyperæsthesia or anæsthesia is unilateral, and becomes then rather a localizing symptom. It will be seen that our patients had more or less disturbance of general sensation.

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District of the Massachusetts Medical Society, on the occasion of the annual meeting of the State Society, June 11, 1888.

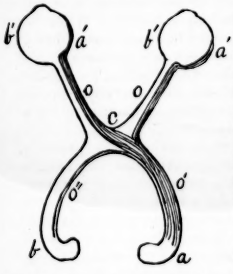
Dizziness, staggering and general weakness, or weariness, are the more common general motor symptoms. It is not possible to connect these with any particular seat of the tumor, though when severe they may give rise to suspicion of diseases of cerebellum or the peduncles of the brain. These symptoms are not always very decided. There may be merely a slight sense of unstable equilibrium on change of position from reclining to upright, or the reverse. The weakness may be simply a sense of general weariness, a feeling of inability to walk as far or do as hard work as formerly.

Variations in the superficial and the deep reflexes are quite common in cerebral tumor. Perhaps these are in a measure localizing, as they are present on the same side with the paralysis, if that exists.

Mental disturbance belongs to the general symptoms. It was present in these cases in various degrees, from simple habitude to decided dulness, loss of memory and unconsciousness. It is difficult to decide whether the attacks of unconsciousness in the first case were due to the general or diffused influence of the tumor, or were not due to local disturbances. As the disease progressed the mental dulness was marked in all the cases. I think there was no insanity in any of them, yet this is sometimes clearly marked as dependent upon a tumor of the brain.

Vomiting is rather common. When present it is a valuable symptom. It is sometimes very obstinate, resisting all treatment or means to alleviate it. It is most common in tumors affecting the medullar and cerebellum, especially the middle lobe. There may be nausea without vomiting.

Optic neuritis is a very valuable symptom for diagnosis. If the other symptoms are obscure, if there is doubt as to their importance, and it seems impossible for such slight disturbances to signify so grave a change, the ophthalmoscope may decide the question. If optic neuritis is present the most trifling symptoms acquire an immense importance. The neuritis may be absent, but if present it is not to be underestimated. In some of my cases the other symptoms so decidedly pointed to tumor, and the patient was in such a condition the ophthalmoscope was not used.



Besides the general symptoms which are common to most cases of tumor of the brain, and have no localizing value, one symptom which is of importance in the diagnosis of the situation of the tumor is found in three of the following cases. I refer to hæmianopsia. In two of the cases there was homonymous lateral hæmianopsia, and in one case this was double, giving rise to total blindness.

The fibres of the optic nerve partially decussate in the optic chiasma (c); so that those passing from the right side of the brain (a) supply the right half of each eye (a' a'). The rays of light from an object to the left of the median line will fall on the right half of each retina, and the impressions thus produced will be carried through the optic nerves (o, o) and the right optic (o') tract to the right side of the brain (a.) Any destructive lesion, therefore, of the optic tract or the nerve centres on the right behind the optic chiasma will cause loss of vision for objects to the left of the patient. This is left homonymous lateral hemianopsia. If there is paralysis due to the same lesion, the loss of vision affects that half of the field of vision which corresponds with the side of the body which is paralyzed.

The word hemianopia is used with reference to the loss of function in the retina. Hemianopsia is used with reference to the field of vision; therefore, as the rays of light cross from right to left after entering the eye, right hemianopsia corresponds to left hemianopia. American authors seem to prefer hemianopsia. Most English authors, except Ross, use hemianopia.

Hemianopsia may be caused by lesion of one optic tract behind the chasm. It is also caused by lesion of the external corpus geniculatum, the anterior corpus quadrigeminum, that portion of the optic thalamus called the pulvinar, and the cuneus in the occipital lobe.

The first case is of interest on account of the disturbance of sight. It is a case of right lateral hemianopsia due to lesion of the left optic thalamus. The disturbance of speech is not explained by the lesions found. The disturbance of sensation, anæsthesia with analgesia, and the partial loss of motor power, were probably caused by pressure of the tumor upon the posterior part of the internal capsule. It is quite possible that the tumor may have implicated the sensory tract in that portion of the internal capsule. The deafness may have been caused by the lesion of the above sensory region, otherwise it is not explained by the autopsy. The fact that the loss of sight increased, the left eye became entirely blind, the right nearly so, would be reason for considering the left optic thalamus as the original seat of the tumor, and as it increased in size it extended to the right optic thalamus and the right anterior corpus quadrigemium.

It is to be regretted that Dr. Gannett did not receive the brain in a more perfect condition, but the examination he was able to make is well described, and nothing has been assumed beyond that which the brain showed.

CASE I. Headache, attacks of unconsciousness, right hemiplegia, right hemianopsia, right hemianæsthesia, with hyperalgesia, disturbance of speech, left amblyopia; tumor in region of optic thalmi and corpora quadrigemina.

C. M., aged thirty-two, seen in April, 1882, was said to have had headache for many years, sometimes very severe, so that he would walk the floor groaning; between these severe attacks, which recurred once in three or four weeks, his head would be easier, but not entirely free. He had always drank more or less spirit, and at the time his illness began, in September, he had drank more than usual. In September he complained of being unusually tired and weary, and was restless at night, waking often and complaining of being tired. Some weeks later, perhaps in November, he had attacks of loss of consciousness, generally once a day; these continued till about January. During this time he had trouble with his head, rather different from his former disturbance. After November, exactly the date was not remembered, he complained of numbness in his right foot, and later, in his right hand. This numbness increased, and gradually he lost skill in the use of his limbs, wrote poorly, so that

his hand-writing was scarcely legible. In January the attacks of unconsciousness ceased, and in their stead he had distressed spells. One of the attacks of unconsciousness was seen by his physician. Mr. M. said he was about to have an attack; his eyes changed their expression, and he soon slowly rotated his head to one side, then to the other, then began to swallow; this continued two or three minutes. He then sighed, and soon after recovered consciousness; was slightly confused; had no increase of distress in head afterwards. After January the attacks were without loss of consciousness, there being simply general distress, during which he did not wish to be touched; his wife said he looked as if he were about to die. He had from three to six a day. Six weeks before he was seen, one of these attacks was so severe he was put to bed; he did not get up again to stay up. At that time he had lost most of the motor power in his right arm and leg; he could walk only with difficulty; said he was dizzy, but seemed to stagger from weakness of the right leg, rather than from vertigo. After he was confined to bed, during the six weeks, he was much of the time free from headache, had only two or three severe attacks, and for four or five weeks had had no attacks of distress. Just before he took to his bed he began to have right lateral hemianopsia, vision being lost for objects on the right of the median line. During the six weeks the strength in his right leg did not vary much. It could be moved a little; the right arm varied, some days being moved better than on others.

His wife said that, even early in the disease, he had trouble in talking, using the wrong words, miscalling the names of his friends, and sometimes he was scarcely to be understood. When he wished to have the right arm moved, he asked his wife to bring him the fly-paper and put it on the bed. At times he swallowed slowly. Bowels generally regular, but for a few days he had had small involuntary motions. Micturition was normal.

When seen the right pupil was larger than the left, but both reacted to light; the right eye opened wider than the left, and did not quite close; both eyes moved naturally. There was loss of vision for objects to the right of the patient in both eyes — right lateral hemianopsia; there was partial facial paralysis on the right. The tongue protruded straight; he swallowed without trouble. His right hand was almost motionless, though he could close the fingers when flexing the arm. There was no contraction; the right leg could be moved and raised from the bed, but less strongly than the left. Sensation was diminished throughout the right side, but there was hyperæsthesia to pricking, scratching and pinching, the sensation being very unpleasant. Hearing was much diminished on the right. The plantar, cremaster, and abdominal cutaneous reflexes were absent on the right, well marked on the left. Tendon reflex was well marked, perhaps rather exaggerated on both sides. Ankle clonus was well marked on the right, absent on the left. There was no tremor. The ophthalmoscope showed the arteries small, the veins large, but the discs were not essentially changed from normal. The pulse was 84, small, and feeble; the heart-sounds faint; no murmur.

About a month later the report was that he mixed names more; speech had somewhat improved. He had had pain in the left temple, had had photophobia in a bright light, had been entirely blind in the left eye, had great general hyperæsthesia.

June 5th. He had sinking spells, panting for breath. This lasted long, intelligence diminished constantly, and he took less notice of his surroundings. The left eye was totally blind, and vision in the right eye was dull.

June 10th. Coma, which deepened, and from the 12th he showed no sign of consciousness. He could not swallow. There was no marked paralysis of the upper branches of the seventh nerve, no conjugate deviation of the eyes; the paralysis was not changed, except to become more complete. As he passed into coma, the temperature rose to 103°, and a short time before death it was 102+°; the pulse was 160 or more, very feeble.

An autopsy was made by a neighboring physician, and the brain was sent to Dr. W. W. Gannett, who has furnished the following description: The brain "was rather soft, but still in sufficiently good condition to enable one to say that the cortex and white matter, as well as the membranes, were in a normal condition so far as gross appearances were concerned. The interesting portion was the basal region, but this, unfortunately, had been cut so irregularly that it was very difficult to get the exact relation of the parts. Putting the parts together as well as I could, the condition was about as follows: The posterior inferior part of the right optic thalamus in the immediate neighborhood of the corpora quadrigemina was occupied by a nodule about the size of a filbert meat, of a red color and rather soft consistency. The anterior corpus quadrigeminum on the right was probably implicated. This nodule was shown in section, on a cut which had been made antero-posteriorly and vertically about the middle of the pons. What I take to be the left optic thalamus was occupied through its whole middle and posterior portion by a red, soft mass, like that seen in the right thalamus, and which was probably continuous with the latter. Altogether, the mass must have been the size of a small plum.

"On microscopic examination, the nodule was found to be made up of medium and large-sized cells, with single, well-marked nuclei; the form of the cells was either a long oval or spindle shape. They were exceedingly numerous, lying in close contact, and no interstitial substance could be made out. There was an abundant development of large and small bloodvessels, and also evidence of earlier small hæmorrhages into the mass. The mass represents a sarcoma of a very vascular variety, and, judging from the appearance of the cells, I should say of a tolerably rapid growth.

The second case is remarkable for the large number of tumors in the brain substance. Thirty-two were counted and most of these located, varying in size from the sixteenth of an inch to an inch and three-quarters in diameter. It is useless to refer special symptoms to any one tumor, yet it is of interest to note, in relation to the loss of sight that both occipital lobes contained rather large tumors; and on the left the internal capsule may have been injured in its motor tract, either by pressure or by the destruction of its fibres by one of the growths.

As in other cases of melanotic growths the tumors were found in other organs, the bronchial glands, mesenteric glands and in the intestines.

Case II. ——, aged thirty-two, had enjoyed perfect

health so far as known by himself and friends, until about eight years ago, when he had rheumatic fever, from which he fully recovered. October 19, 1881, he first noticed slight dimness of vision with pain in his eyes, which was increased by any attempt to use them. About two weeks later he felt pain in the back of his head and neck, from which he suffered more or less until about the first of December; the pain then abated leaving a feeling of distress in the same region. He was unable to fix his mind on any subject or follow out any train of thought, was easily fatigued, unsteady in his gait, and complained of a general feeling of weariness and weakness of the legs.

About the first of December his left eye was seriously affected, the right was less so; this was supposed to be due to partial loss of accommodation. About the middle of December he began to have attacks of vomiting without nausea; these recurred once in four or five days until January 27th, when Dr. Gilbert was called to see him, he having vomited fifteen or twenty times. He had then practically lost the sight of his left eye, and the field of vision was quite limited in the right. His mind was clear but weak, he then suffered no pain; temperature and respiration were normal, pulse 65. During the afternoon an attack of singultus began which continued about twenty-four hours; similar attacks recurred at intervals during the next three weeks, but less violent. The urine was normal, contained neither albumen nor casts.

During a part of December and January he was obliged to keep his bed, during a part he was up and even went out to ride; he had difficulty in walking, staggering.

I saw him January 29, 1882. At times his speech was defective; his headache less intense, but from the motion of his head and from his putting his hand to his head, it was probable that he still had some discomfort. He talked with difficulty, was languid and apathetic.

The left eye was a little more prominent than the right, there was a slight nystagmus, the face showed a slight loss of tone on the right, though there was no paralysis; the eyelids closed well on both sides, the tongue was protruded straight. The right arm and leg were weaker than the left. He staggered on standing and required support. There was extensive hæmorrhagic retinitis in both eyes, the discs being obscured and the vessels showing only in a part of their course; there was not much difference between the two eyes.

The diagnosis was tumor, probably in the cerebellum, and it was thought most probable that the middle lobe was involved and that there was pressure upon the left side of the medulla oblongata.

Mercurials and iodide of potassium were given and he improved for about a week, he then vomited and was much worse for a few days; with slight remissions and occasional exacerbations he grew steadily worse till he died.

About February 5th or 6th he became totally blind. February 17th and 18th he was nearly if not quite unconscious, breathing was labored, he took no food and could scarcely be aroused sufficiently to swallow a few spoonfuls of water. On the evening of the 18th he began to improve, slept well that night and the next day was quite rational and talked much. On February 15th, he began to pass his urine involuntarily. February 21st his hearing began to fail, and after a little he became totally deaf. On the 24th he had another ill turn, was unable to swallow, scarcely moved his right side; his head was turned to the left and his eyes were directed upward and to the left, the pupils widely dilated, the left more than the right, there was slight divergent strabismus. He was quite unconscious, breathing heavily and irregularly. In the evening he began to regain consciousness and for the next three days was brighter, especially in the morning. February 25th he talked much, but was so deaf that it was very difficult to make him hear. He sweat profusely for two hours. There was almost complete anæsthesia of the right cheek, the sensitiveness of the left was much diminished, but he was quite sensitive about the lips and eyes. Temperature and respiration were about normal, pulse varied from 65 to 72. After this for three or four days he was more conscious, talked considerably, relished his food, slept much of the time. For ten days he again was nearly unconscious, noticed nothing, the conjugate deviation of head and eyes mentioned above still persisted, there was nystagmus, the eyes did not, however, pass to the right of the median line. March 17th to April 3d he was again partially conscious, seeing and hearing nothing, he knew no one and imagined himself away from home. Smell and taste were very acute, he was aware that he was blind, but did not realize that he was totally deaf.

He had another febrile attack with increasing stupor, pulse running up to 160, respiration 56, and temperature 101°. From this he revived, pulse going down to 76, respiration and temperature to normal, and he again talked much. At this time the head and eyes, instead of being turned persistently toward the left, as they had been for weeks, resumed their normal position and action, the pupils were still largely dilated, and the right more so than the left. This condition continued for thirty-six hours, when they were again turned towards the left and remained so till death; the pupils varying, generally dilated. April 17th he began to fail again, and May 5th he died.

Autopsy. Body very much emaciated; skull very thin, inner table very rough with many sharp spiculæ projecting inwards, there was scarcely any diploe, and in several places there was entire absorption of the inner table. The veins of the dura mater were quite full. Pachionian bodies moderately prominent; there was a soft clot in the longitudinal sinus; veins of the pia mater were very much distended. On both sides of the longitudinal fissure just anterior to the fissure of Rolando, the pia mater was thickened and yellowish-white in color. This on being removed did not bring with it any cortical substance. The convolutions were well filled and the sulci not prominent as seen through the pia mater.

Throughout the substance of the brain were scattered a large number of small tumors, of a dark, almost black color, but on section somewhat mottled, if large, irregularly lobulated. Under the microscope these were seen to be composed of round, fusiform or candate cells, rather small, generally filled with pigment, only loosely connected together by a very small amount of connective tissue, the masses were very rich in bloodvessels.

The locality of these tumors was as follows: In the left hemisphere, directly opposite the extremity of the fissure of Sylvius on the surface of the supra-marginal

gyrus, was one three-quarters of an inch in diameter; just at the point where the perpendicular fissure comes to the upper convex surface was one lying rather deep, and nearly concealed by the overlying brain substance; in the longitudinal fissure posterior to the perpendicular fissure was one one-fourth inch in diameter; at the extreme end of the occipital lobe, on the under surface near median fissure, was one with a lobular conformation one and one-half to one and three-fourths inches in diameter; around this the cerebral tissue was more softened than elsewhere; near the middle of the parietal convolution was one three-fourths inch in diameter, covered by cerebral tissue; near the junction of the second and third temporal convolutions, in the third and near its middle longitudinally, was one about one-fourth inch in diameter; just to the left anterior part of the left olfactory nerve was one one-fourth inch in diameter; under this nerve was a very small one one-sixteenth inch in diameter. In the right hemisphere, within the median fissure in the occipital lobe, was one nearly an inch in diameter; a little below this, at the extreme posterior extremity of the occipital lobe, three-quarters of an inch from the under surface, was one three-fourths inch in diameter; on the under surface, near the tentorium, there were two, each about one-fourth inch in diameter; a small tumor, one-sixteenth inch in diameter, was in the pineal gland.

The membranes in the fissure of Sylvius and around the optic chiasm were rather thickened and matted together. The bloodvessels at the base were pervious and healthy.

Scattered through the interior of the right hemispheres from vertex to the level of the lateral ventricle there were ten tumors, varying from one-twelfth to one-half inch in diameter. On the left side in the same region there were six. On the right side, in posterior part of the tail of the caudate nucleus, projecting slightly into the lateral ventricle, but covered by a thin layer of cerebral tissue, was a tumor one-half inch in diameter; the surrounding cerebral tissue was softened. In the anterior portion of the lenticular nucleus, near its upper surface, extending across the external capsule to the claustrum, was one one-half inch in diameter. On the left side, about the centre of the caudate nucleus, projecting into the internal capsule, was one one-half inch in diameter; rather above this, in the lenticular nucleus, was one one-eighth inch in diameter. On right side, in middle of cerebellar peduncle, just above the point of exit of the fifth nerve, was one one-half inch in diameter; in the left lobe of the cerebellum, near its outer surface, were two, one below, the other above, both one-half inch in diameter. The right lobe was free.

The base of the skull presented a similar appearance to the calvarium in roughness and absorption of inner plate.

Thorax: pericardium was universally adherent; the two pleural cavities contained about six ounces of clear fluid. The left lung was healthy, but at the base, near the entrance of the bronchus, a bronchial gland presented a melanotic appearance. The lower lobe of the right lung was solidified in its posterior part; contained no air. Heart and its valves were healthy; the right cavity contained soft coagula. Walls of the heart were very firm.

Abdomen: liver and spleen were both abnormally small and firm, the latter measuring two by one and one-half by one-half inches. Kidneys were small, but healthy. Stomach presented only post-mortem changes. Some of the mesenteric glands were enlarged, and, on section, had a dark color, resembling the tumors found in the brain. About a foot below the stomach was an invagination of the intestine, estimated to be about ten inches long, and about a foot below this was another about six inches long. There was no swelling and no marked congestion around these invaginations. In the shorter portion of intestine thus invaginated was a small, pedunculated, melanotic tumor, about one-half inch in diameter.

In the third case there was left hemianopsia. The left hand showed great loss of coördination. Gowers has given a drawing of a tumor just beneath the corpora quadrigemina, which he considers was the cause of a similar incoördination. This locality would explain the hemianopsia, and also the paralysis of the motor nerves of the eye.

The spasm of the right arm was described as if of cortical origin; it was a simple case of monospasm. The seat of the lesion causing this spasm must have been in the cerebral hemisphere, not in the mesencephalon, for there was conjugate deviation of the head and eyes to the right, towards the side affected with spasm. The law in regard to conjugate deviation is that in lesion of the hemispheres the deviation is toward the affected hemisphere in paralysis; as it has been said, the patient seems to be trying to look at the injury. In spasm the deviation is towards the unaffected hemisphere, towards the limbs which are convulsed.

If, then, the report given me of the side affected with spasm was correct, and I think it was, there must have been two centres of disturbance: one in the cortical motor centre for the arm on the right, which was not sufficient to cause paralysis; a second in the vicinity of the anterior corpus quadrigeminum and pulvinar, giving rise to the other symptoms.

As there was the history of former tubercular disturbance in the lung, it is probable the lesion was tubercular, and we know that such tumors in the brain may be multiple. There was no autopsy to confirm this diagnosis.

Case III. Mrs. W. was seen with Dr. J. W. Willis. Her former physician said that she had lung trouble, and this opinion was confirmed by Dr. E. H. Clarke. She went to California, where she seemed to have recovered, and recently the lungs had given her no trouble.

She was married December, 1881. In February or April, 1882, she had a spasm of the right arm, which drew up. Then she lost consciousness. There was no other spasm until April, 1887, then in May, and on July 31st of the same year she had other spasms of the right arm. She saw the arm draw up, there was a sensation as if the fingers were being torn out, then she lost consciousness. She bit her tongue and her head turned to the right, and her eyes to the right. There was conjugate deviation of head and eyes to the right. She was very nervous lest she should have another attack.

After July, 1887, she took less interest in what occurred about her. Her mental condition changed in a way that it was difficult to describe. She was rather apethetic, indifferent to her surroundings, and this condition grew gradually more marked.

About Thanksgiving she had headache. She did not have this previously. The pain became more in-

tense. She was dizzy, was weak during two or three weeks before I saw her. During the previous two days there was diplopia.

When seen there was external strabismus, the notes do not say of which eye. The left side of the face acted less readily than the right, the left eye was more widely open, and the left pupil responded less readily to light. The tongue was protruded straight. Hearing was seemingly less acute on the left, but at times she was not easily aroused, and the observation might not have been accurate on that account. There was left hemianopsia, the line of demarcation passing through nearly the centre of the visual field.

The grasp of the hands seemed about equal on the two sides; but there was great loss of co-ordination on the left, that hand moving in a very disorderly way when an attempt was made to touch the nose with the eyes shut. Sensation seemed equal on the two sides. The superficial and deep reflexes of the legs were equal on the two sides.

The next case is allied to the last by the spasm. It differs from the two previous cases in there being no disturbance of sight, and it is probably not a case of tumor. Fortunately, the improvement has been so great that there is no probability of death at present.

This is a typical case of localized irritative lesion of the cortical motor centre, progressing to partial destruction, or at least abolition of function, with subsequent recovery. The gradual extension of the pathological process from the centre for the feet near the median fissure, down both sides of the central fissure, as the arm and body, then neck and face became involved, can be distinctly recognized by the extension of the symptoms to those parts of the limbs and body.

The improvement is encouraging and instructive. Having decided as to the locality and probable nature of a lesion and the possibility of relief, we should persistently follow the course indicated even when there is seemingly no immediate gain. In one other similar case I have found benefit from large doses of iodide of potassium and mercury where it seemed that death must be close at hand. The spasms, beginning in the face and extending to the arm, then to the leg, recurred every three minutes for many hours. The patient recovered from that attack, but subsequently died.

CASE IV. Miss H. was seen early in November. She was past the climateric. She had fairly good health until four years previous to visit, when she had some anxiety about one of the family. The first disturbance to attract attention was a twitching of the left leg; then she became unconscious. Her head and eyes were turned to the left (left conjugate deviation of head and eyes).

For a long time, how long was not known, there was no symptom, then she had at times a slight drawing sensation in the left ankle. Later this extended to the left leg, then to the left thigh. At times the left leg moved spasmodically. There was at these times no loss of consciousness, no pain, no loss of sensation. The phenomenon was purely motor.

Still later the same spasm affected the left arm, and recently the left side of body and the left side of neck and face. There were no general convulsions. Lately there had been pain in the left leg, a heavy aching, though sometimes severe pain. There was also some numbness.

The left hand and arm had always been smaller than the right. The left leg was one-eighth inch smaller round than the right. The patellar tendon reflex was the same on both sides. Sensation was about the same on both sides.

She could not use her left hand readily. She dragged her left leg, and walked lame. The eye, pupils, tongue and face moved naturally. She was intelligent. Her mind seemed fairly active.

The diagnosis was clearly some irritation of the motor centres in the cortex. The symptoms did not point to a tumor. There were none of the general symptoms of tumor present. A localized chronic meningitis would explain the symptoms. Acting on this theory I advised iodide of potassium in large doses, with moderate doses of bromide of potassium.

Dr. Julia Tolman took charge of the patient, and I am indebted to her for the subsequent history of the case.

After nearly four weeks the pain was less, sleep was better, the spasms of wrists and ankles, which had recurred frequently, had ceased. There was much more loss of power in the arm and leg. The patient stumbled often in walking, and had more difficulty in raising her foot from the floor. She could not raise her hand to her neck. The patient was at that time taking twenty-five grains of iodide potassium and twenty grains bromide of potassium three times a day. Her friends objected to her taking large doses because they were afraid the loss of power might be caused by the medicine. Yet they had been expressly warned that the disease would lead to such loss of power.

A short time after a slight œdema of the legs appeared, but the urine was free from albumen. Iodide of mercury was given for a short time with the iodide potassium. Fifty-three grains three times a day of the latter seemed to slightly disturb the stomach, so the amount was reduced to thirty-five grains.

About two months after she was first seen the paralysis was steadily increasing. There was no pain. The mind seemed less clear. Sometimes she seemed rather stupid.

In February she began to improve. Could use her hand a trifle better, could walk better. She had grown stouter. Her general health was good. At that time she was taking from forty-five to fifty-three grains of the iodide and fifteen of the bromide three times a day.

Towards the end of May the report is very favorable. There had been a decided improvement during the previous two months. She could walk fairly well without support, dragging the left foot a little. The hand, which was for a time absolutely powerless, could be extended and flexed a little, and raised nearly to her shoulder. A feeling of constriction about the waist, distension of bowels and incontinence of urine, which had been somewhat troublesome, had entirely disappeared. She still continued forty five to fifty grains of the iodide of potassium.

— Professor Billroth, who led the opposition, a few years ago, to the admission of women to the continental medical schools, has created something of a sensation in Vienna, it is reported, by having Dr. Grace Wolcott and three other American women physicians repeatedly in attendance at his private clinic lately, to witness his own operations. — *Med. and Surg. Reporter.*

REPORT ON PROGRESS IN SURGERY.[1]

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

LAPAROTOMY FOR ACUTE INTESTINAL OBSTRUCTION, WITH ABSTRACTS OF 69 CASES.

ROCKWELL [18] has made a careful analysis of 69 cases, and finds the mortality in the decade between 1877 and 1887 is 46%, or a gain on the statistics previous to 1873 of 27%, and "this in spite of the fact that nearly two-thirds of the fatal cases were operated upon at a time which would almost necessarily preclude successful results."

Dividing these cases into groups, according to cause, and giving the mortality, we have:

	Recoveries.	Deaths.	Total.
Intussusception	6	5	11
Bands or adhesions	14	10	24
Volvulus	3	4	7
Biliary or intestinal calculi	1	3	4
Diverticula	0	4	4
Unclassified	13	6	19

Again, we must insist that the time has come when an early exploratory laparotomy in these cases is imperative.

MYXŒDEMA.

The Committee of the Clinical Society of London have made a report,[19] of which the following are the conclusions:

(1) That myxœdema is a well-defined disease.

(2) That the disease affects women much more frequently than men, and that the subjects are, for the most part, of middle age.

(3) That clinical and pathological observations respectively indicate, in a decisive way, that the one condition common to all cases is destructive change of the thyroid gland.

(4) That the most common form of destructive change of the thyroid gland consists in the substitution of a delicate fibrous tissue for the proper glandular structure.

(5) That interstitial development of fibrous tissue is also observed very frequently in the skin, and with much less frequency in the viscera, the appearances presented by this tissue being suggestive of an irritative or inflammatory process.

(6) That pathological observation, while showing cause for the changes in the skin during life, for the falling off of the hair and the loss of the teeth, and for the increased bulk of the body, as due to the excess of subcutaneous fat, affords no explanation of the affection of speech, movement, sensation, consciousness, and intellect, which form a large part of the symptoms of the disease.

(7) That chemical examination of the comparatively few available cases fails to show the general existence of an excess of mucin in the tissues adequately corresponding to the amount recorded in the first observations, but that this discrepancy may be in part attributed to the fact that tumefaction of the integuments, although generally characteristic of myxœdema, varies considerably throughout the course of the disease, and often disappears shortly before death.

(8) That in experiments made upon animals, particularly on monkeys, symptoms resembling in a very close and remarkable way those of myxœdema have followed complete removal of the thyroid gland, performed under antiseptic precautions, and with, as far as could be ascertained, no injury to the adjacent nerves or to the trachea.

(9) That in such experimental cases a large excess of mucin has been found to be present in the skin, fibrous tissues, blood, and salivary glands; in particular, the parotid gland, normally containing no mucin, has presented that substance in quantities corresponding to what would be ordinarily found in the submaxillary gland.

(10) That the full analysis of the results of the removal of the thyroid gland in man demonstrates in an important proportion of the cases the fact of the subsequent development of symptoms exactly corresponding to those of myxœdema.

(11) That in no inconsiderable number of cases the operation has not been followed by such symptoms, the apparent immunity being in many cases probably due to the presence and subsequent development of accessory thyroid glands, or accidentally incomplete removal, or to insufficiently long observation of the patients after operation.

(12) That, whereas injury to the trachea, atrophy of the trachea, injury of the recurrent laryngeal nerves, injury to the cervical sympathetic and endemic influences have been, by various observers, supposed to be the real causes of experimental or of operative myxœdema (cachexia strumipriva), there is, in the first place, no evidence to show that, of the numerous and various surgical operations performed on the neck and throat, involving various organs and tissues, any one save those in which the thyroid gland has been removed, has been followed by the symptoms under consideration; that in many of the operations on men, and in most, if not all, of the experimental operations made by Professor Horsley on monkeys and other animals, the procedure avoided all injury of surrounding parts, and was perfectly aseptic; that myxœdema has followed removal of the thyroid gland in persons neither living in, nor having lived in, localities the seat of endemic cretinism; that, therefore, the positive evidence on this point outweighs vastly the negative, and that it appears strongly proved that myxœdema is frequently produced by the removal, as well as by the pathological destruction of the thyroid gland.

(13) That whereas, according to clause 2, in myxœdema women are much more numerously affected than men, in the operative form of myxœdema no important difference of the same kind is observed.

(14) That a general review of symptoms and pathology leads to the belief that the disease described under the name of myxœdema, as observed in adults, is practically the same disease as that named sporadic cretinism when affecting children; that myxœdema is probably identical with cachexia strumipriva; and that a very close affinity exists between myxœdema and endemic cretinism.

(15) That, while these several conditions appear in the main to depend on, or to be associated with, destruction or loss of function of the thyroid gland, the ultimate cause of such destruction or loss is at present not evident.

CANCER AND CANCEROUS DISEASES.

Paget, in an extremely interesting and suggestive article,[20] calls attention to the likeness existing between cancers and innocent tumors on the one hand,

[1] Concluded from page 249.
[18] Ann. of Surg., Feb., 1888, p. 81.
[19] Lancet, June 2, 1888.
[20] Lancet, Nov. 19, 1888.

and specific and micro-parasitic disease on the other. Paget believes that as it is now demonstrated that every specific disease is known to be the result of some distinct morbid substance, that we shall eventually find that there is some micro-parasite or substance that is essential to the production of cancer. Further he considers that cancer is allied to the group of specific disease, including syphilis, tuberculosis, glanders, leprosy, and actinomycosis. They are all essentially morbid growths, self-maintaining; have special modes of degeneration and of ulceration, to which they all tend; are all at some time either infective to parts far off by transmission of particles through lymphatics or bloodvessels, or to adjacent parts by invasion, or to other beings by inoculation; they all occur in parts, by preference, subject to local injury or irritation. These he considers are strong likenesses, and as we know that in tuberculosis, syphilis, and leprosy, there is in each case a specific morbid material in the blood, so we should believe that there is one in cancer. Sir James Paget, in concluding this admirable lecture, believes that we may reasonably hope for a remedy against cancer, as mercury and quinine are against syphilis and malaria.

GRAFTING.[21]

Surgeons are familiar with skin grafting in the human subject, but it is rather a novel procedure to substitute the skin of birds and poultry for snips from the patient's own healthy skin. Wiesmann twice transplanted skin from pigeon to pigeon with success and three times from fowl to fowl. Under the title of *Dermepenthesis*, Mr. G. F. Cadogan-Masterman published some interesting cases in which he had succeeded in utilizing the skin of young wild rabbits for the purpose of bringing about the cicatrization of raw and ulcerating surfaces. Several others have repeated and varied Wiesmann's experiments, but before Mr. Masterman none of them seem to have been enterprising enough to spare their patients the disagreeable snipping incidental to the operation as it is usually practised. At about the same time Dr. Redard communicated to the Paris Academy of Medicine some observations of his own with animal grafts on wounds in human beings. In a case of severe burn of the scalp of eight months' standing, in a child two years of age, he obtained rapid cicatrization by means of grafts from a fowl. He first tried grafts of frog's skin, but as these proved to be repulsive to patients, and did not give very good results, he substituted others from the fowl, and the wound, which measures three inches by two and a half, had completely healed in two months. He had been equally successful in other and subsequent cases. He takes the skin from beneath the wing of a chicken, carefully securing the subjacent cellular tissue, but avoiding adipose tissue. The transplanted pieces varied from a sixth to a third of an inch in size, and they were maintained in position by means of a little cottonwool and iodoform gauze. The skin of birds and fowls has the advantage of being supple, delicate and vascular; it adapts itself readily to the surface of the wound, and adheres without undergoing absorption.

Senor F. Altramirano mentions in a Mexican journal, *El Observador Médico*, a case in which he made some experiments in skin grafting on an obstinate ulcer left by a large carbuncle.[22] More ordinary means having failed to cause it to heal, he applied three skin grafts taken from the patient himself. Of these only one took, and the man expressed so much repugnance to the proceedings that another source had to be found for subsequent grafts. A cock was selected and fragments cut from his gills; these were split, divided into ten pieces, and the raw surfaces applied to freshened portions of the ulcer. A carbolized dressing was then bandaged on, the whole being constantly moistened. On the third day, on the dressing being removed, all the ten fragments were found organically adherent. A number of new grafts were then applied, cut from the comb, the gills, and the skin of the back of a chicken. None of these were successful. The cock's gills were again resorted to, and four more fragments successfully grafted. A fresh set of grafts were prepared from this source; but all the cellular tissue was cut or scraped away, in some cases little but the epidermis being left, in others the edges being bevelled, so that the epidermis was in direct contact with the new surface of the ulcer. This set of grafts proved very unsuccessful, so that Dr. Altramirano was led to the conclusion that no advantage is gained by applying the epidermic layer immediately in contact with the surface of the ulcer.

STERILIZED DRESSINGS.

Schlange's[23] experiments led him to believe that the ordinary dressings "aseptic" are not so. Blood and albuminous fluids render inert sublimate dressings. Soaking in boiling water or a sufficiently strong sublimate solution, and immediately applied, is truly aseptic, but such wet dressings have numerous disadvantages, for example, prevention of evaporation of wound secretion, tendency to produce eczema, hence applicable only in suitable cases. Routine dressings must be dry, as ordinarily prepared dry dressings contain infectious germs. Hence sterilized dressings are substituted prepared by von Bergmann as follows, and used exclusively by him with admirable results. The raw material, cut as desired, is exposed in a wire basket in an oven, to superheated steam for one hour: after removal and drying for a minute, the basket, with untouched contents, is put in an iron cylinder, from which the gauze is withdrawn as required. This secures with the minimum of handling an absolutely germ-free material. Schlange thinks that the speedy and undisturbed evaporation of wound secretion important for the healing of wounds. Decomposition of blood or discharges in a sterilized aseptic dressing is only possible from the action of germs alighting on its surface; mere staining twenty-four hours after an operation of the superficial layers, does not require renewal. No risk involved if evaporation is favored by patient's position, etc. Extensive soaking of dressing require renewal of superficial layers; deep layers beginning to dry should be left undisturbed.

DISINFECTION OF SURGICAL INSTRUMENTS AND DRESSINGS.

Renard,[24] in an elaborate article, finds that the disinfection of instruments by a five per cent. solution of carbolic acid is unreliable, the germs withstanding a soaking of from thirty to forty-five minutes. Bichloride is reliable, but has a chemical action on the instruments. Flaming, if thorough, is efficient. Boil-

ing at 212 F. is efficacious, if long continued. Steam at 230 F. destroys all germs, if the substance be submitted to it for thirty minutes. Renard has a copper cylinder boiler that he fills about an eighth full of water; baskets containing instruments, and provided with feet that raise them from the surface of the water, are put in the cylinder, a lid containing a manometer and a safety-valve is screwed in place, and by means of an alcohol lamp the water is boiled, the air in the cylinder passes off by a stop-cock in the lid, which is then closed, and the pressure is increased until it represents a temperature of 230 F. Absolute disinfection is obtained in a half of an hour. Sponges are not subjected to this temperature, and instruments are never subjected to a temperature of more than 245 F. He draws the following conclusions:

(1) Disinfection by steam compressed at 230 F., as applied in the apparatus above described, is certain and practical.

(2) Instruments or dressings submitted to this treatment for fifteen or twenty minutes are absolutely disinfected.

(3) The apparatus is very simple, not dangerous, and can be trusted to a nurse.

(4) Neither dressings nor instruments are in any way altered by a prolonged treatment, if the temperature does not exceed 230 F.

DRESSING FOR CIRCUMCISION IN ADULTS.

Ballance[25] describes his method of dressing the penis as follows:

When the patient is etherized, the outline of the posterior border of the glans is marked on the skin with an aniline pencil. The skin of the prepuce is slit and removed up to the aniline line. The mucous membrane is next cut away, leaving only a free edge of about one-eighth of an inch in width. Any bleeding which occurs should be entirely arrested, and asepsis must be insured by frequent sponging with carbolic or sublimate solutions. Numerous horsehair stitches are then inserted, so as to bring accurately together the fresh-cut edges of the skin and mucous membrane, and subsequently, after a further sponging and drying, a piece of gauze two layers in thickness, and wide enough to reach from the root of the penis nearly to the meatus, is wrapped *loosely* round the penis, and secured by several applications of the collodion brush. The setting of the collodion is hastened by the use of a fan, so that the air is kept in motion, and the patient should not be allowed to recover from the anæsthetic till the dressing is quite firm and hard.

In this manner the penis is protected by a kind of carapace, and the patient is relieved from the pain and tenderness attendant upon contact with the bedclothes or other objects. In fact, the organ can be handled as if no operation had been performed. It is hardly necessary to add that erections, which are under the usual conditions so painful, cannot occur.

The patient never had any discomfort from first to last, and the day after the operation put on his trousers without my leave, and expressed himself as desirous of taking a long walk or of going to business.

APPARATUS FOR THE STERILIZATION OF INFANT FOOD.

DR. ROTCH presented for the inspection of the Society an apparatus devised by him, by which the infant's food could be given to it sterile, as from the human breast. He remarked that the approach of the warm season made it our duty to adopt every means within our power to prevent the onset of, and to treat when they appeared, those gastro-intestinal disturbances which so frequently were the cause of the high rate of mortality among artificially fed infants. Sterilization of the food was an important addition to our knowledge of such means, and should be given a careful trial. Sterilization as yet had not been so fully adopted in this country as in some parts of Germany, notably Munich, where Professor Soxhlet's apparatus for sterilizing milk was being used in over a thousand families.

Professor Soxhlet has for some years been making investigations of this nature, and his results, and a wood cut showing his apparatus, were published in the *Münchener Medizinische Wochenschrift*, Nos. 15 and 16, 1886. Soxhlet's apparatus, however, although for bacteriological purposes good, is not so useful clinically as it might be; and Dr. Rotch then explained that sterilization was but one factor in having the infant properly fed, and that a proper receptacle for the administration of the food must satisfy the other factors as well as that of sterilization. Quantity was one of these important factors, the infant's stomach growing very rapidly in the first two months, and coming to a comparative standstill in the next three months, thus necessitating a rapid increase in the bulk of the food during the first two months, and very little increase in the next three months.

Dr. Rotch had his attention first drawn to the subject of sterilization by Dr. Ernst in the spring of 1887, Ernst at that time having treated a baby by that method. Dr. Rotch then devised the apparatus, which he considers to best combine all the factors of artificial feeding, in June, 1887, and his article describing his work in this direction, and giving illustrations of his feeding tubes and steamer, appeared in the *Archives for Pediatrics* in August, 1887, Soxhlet's apparatus at that time not being known to him.

During the autumn of 1887, Dr. Rotch also experimented clinically with his sterilizing apparatus during his service in the wards at the Infant Hospital.

The next work of the kind done in this country was that of Dr. Augustus Caillé, of New York, who, following in the footsteps of Soxhlet, and guided by his article, investigated the proper manner of boiling and preserving milk for infants, and his investigations, published in the *Diatetic Gazette* for April, 1888, support the conclusion already arrived at by Soxhlet, Ernst, and others, namely, that milk became sterile when subjected to steam under pressure at 212° F. for from fifteen to twenty minutes. Caille has also had the Soxhlet apparatus made less complicated and more compact.

The next publication on sterilization was that of Dr. J. A. Jeffries, of Boston, in the May number of the *American Journal of the Medical Sciences*, 1888, and his work was more distinctly bacteriological, and was done in Dr. Ernst's Bacteriological Laboratory at the Harvard Medical School, with the same result so far as the length of time found to be necessary for sterilization was concerned, as that of the previous investigators.

Dr. Rotch then said that there were certain points to be noted for clinical purposes.

Where the food is prepared to be given immediately to the infant, one steaming for twenty minutes is sufficient, for we have then killed the developed bacteria; but where the food is to be kept for a number of days it was found that a second steaming was in most cases needed, in order that the spores should also be destroyed.

Dr. Rotch then went on to say that milk could in this way be sterilized and made use of where the infant has to travel for a period of weeks, or whenever a large supply for a number of feedings was desired.

Dr. Jeffries' experiments showed that bacteria were present in Anglo-Swiss condensed milk, and that hence this food should be sterilized as well as those prepared with ordinary cow's milk.

Dr. Rotch explained that his feeding tubes could be used for any of the infant foods, but he wished to draw attention to certain points regarding a combination of milk, cream, limewater and milk sugar which had, in varying proportions, been extensively used by him during the past three years, both in hospital and private practice. First, that this mixture turns brown when steamed, but that this change of color has been found to be innocuous to the infant, and does not contraindicate the steaming. Second, the mixture is decidedly alkaline, while human milk is faintly alkaline. Third, that steaming this mixture renders it neutral, the limewater entering into combination with a portion of the milk sugar, and hence that the limewater if used should not be added until after the rest of the mixture has been steamed.

DR. J. A. JEFFRIES: Dr. Rotch spoke of my work. I examined only one or two kinds of condensed milk. I should not like to say that the bacteria could always be found. I found two kinds, one of which is an ordinary bacterium in this part of the world, and might have got in by standing; and the other I found in moderate amount as a species that is totally distinct from any that has been seen before or since in the laboratory, so that it seems particularly clear that it was not contamination; so I think it rests upon pretty good ground that they do occur here.

As to sterilizing the milk, there are some interesting points. A German investigator has fed dogs, first, with ordinary milk or cow's milk, and then with a mixed diet, and then with sterilized milk, and has examined the fæces for bacteria. When he gets down to the sterilized milk for a certain length of time he claims that the stools become like those of an infant, that is, yellow, and that the bacteria are for practical purposes limited to two kinds: one is the brevis bacillus, and the other one a bacillus which turns the sugar of milk into lactic acid in the absence of air, and seems to be peculiar to the intestines. It is not the same as the lactic acid bacillus, but a different species. These experiments seem to show conclusively that there is something in the sterilization. It seems to me that if we can thus change or prevent the putrefactive processes we shall accomplish a great deal.

DR. S. G. WEBBER read a paper on

CASES OF TUMOR OF THE BRAIN.[2]

DR. P. C. KNAPP: I have listened with very much

[2] See page 277 of the Journal.

interest to these cases of Dr. Webber. There are a great many points of value in them, especially to me. Among them, in the second case which Dr. Webber reports, were the tumors in the occipital lobe, as explaining the loss of vision. It is merely further proof of the views which Munck advanced some seven years ago now, that the centre for vision, as Dr. Webber has said, was in the cuneus and in the adjacent convolutions on the external surface of the occipital lobe. That view was combatted most vigorously by Ferrier, who attacked Munck most sharply for having advanced the theory; but the evidence from human pathology, which has since been collected by Fillegreen (?) and by Seguin, has completely confirmed Munck's views, and the evidence from experimental physiology is also tending thoroughly in that direction. It need only be said that, since 1881, Ferrier has very largely abandoned his position, and, as far as could be expected, is endorsing Munck's views, but still holds that there are other centres; and I am surprised to see that Gowers, in his latest books, still upholds him in his views. Of course, in the case where there are so many tumors, it was doubtful, but it certainly points in the direction that all human pathology has furnished us in that regard.

The hour is getting so late that there is very little that I will say, except that I would like to speak of a case which I have had under observation for several months, which is very closely allied to this one of Dr. Webber. Some two or three months ago, I was asked by Dr. Sumner to see a case in his wards with history of syphilis, having come in with no definite symptoms, but very much depressed, and quite sure that he had some fatal disease — so much so, that he no sooner entered the hospital than he sent for a lawyer to make his will. After entrance he had several convulsions, which were regarded, not by Dr. Sumner, but by some of the other physicians who saw him in them, as hystero-epileptic. They were peculiar attacks, and consciousness was retained through them. I saw him in one of them later on, where consciousness was retained in part, and was told that he would have one whenever you spoke to him. There was conjugate deviation of the eyes and head to the left, with marked spasm of the left arm, and, in the later convulsions, in the left leg also; it began though, I think, in the arm, or possibly in the face, but it was only after he had had a number of convulsions that it extended to the leg. Immediately after the convulsion, the patellar reflex on the convulsed side was markedly exaggerated, and there was a paresis of the left side. During the convulsion there was an involuntary escape of urine. I at once made the diagnosis of some lesion in the cortex, affecting chiefly the centre for the arm and face in the right cortex, although I was unable to determine whether it was a tumor or some meningeal thickening, — some irritant lesion, and, of course, the question of an hysterical attack was settled definitely. Later on, the man had convulsions every fifteen or twenty minutes, became practically comatose, passed urine, and, I think, fæces, in bed, and developed bed-sores, and about that time I feared that he was going to die. In fact, I made that prognosis, and advised the house-officers to tell his friends that probably he would not linger a great while. But I took the advice that he should be given iodides, although, his stomach being rather weak, he could not take them in very large doses — not over thirty grains. Under iodide and mercury alternating, he has made now a very good recovery, and is up and dressed, walking about, with no convulsions, and only a little weakness on that side.

(To be continued.)

Recent Literature.

Operative Surgery on the Cadaver. By Jasper Jewett Garmany, A.M., M.D., F.R.C.S., Attending Surgeon to Out-door Poor Dispensary of Bellevue Hospital; Visiting Surgeon to Ninety-Ninth Street Reception Hospital, Branch of Bellevue Hospital; Member of the British Medical Association, etc. New York: D. Appleton & Co. 1887.

For the purpose for which this book was written, it is admirably adapted in its simple, well-written, and explicit directions. Occasionally the author has sacrificed detail in operative procedure to brevity in style. The absence of plates explanatory of the text is greatly to be regretted, for in teaching a manipulative subject like operative surgery, frequently a rude diagram is worth a whole page of text. We trust that a future edition will allow the correction of this important omission, for in other respects Dr. Garmany has given us an admirable work.

A Manual of the Operations of Surgery, for the Use of Senior Students, House-Surgeons, and Junior Practitioners. By Joseph Bell, M.D., F.R.C.S., Edinburgh; Consulting Surgeon to the Royal Infirmary, and Surgeon to the Royal Edinburgh Hospital for Sick Children. Illustrated. Sixth edition, revised and enlarged. Edinburgh: Oliver & Boyd, Tweedale Court. London: Simpkins, Marshall & Co. 1888.

This work, which was written as a guide to the author's students in years gone by, has passed through six editions, and it is the author's purpose in the present edition to bring the work up to date. We do not feel that the author has accomplished this object, for numerous and glaring omissions of well-recognized operative procedures do not appear in this revised edition. Then, again, the author does not voice the current sentiment in regard to certain operative procedures, as, for instance, he slurringly refers to the use of the galvano-cautery, wire-snares, etc., for the removal of nasal polypi, as procedures which have been devised "greatly to the benefit of the authors' pockets." Some of his statements may be fairly regarded as coming from a man who is ripe in his own experience, and has ceased to be receptive of new ideas. Some twenty pages, for instance, are devoted to the consideration of lithotomy and lithotrity. This is admirably complete, but when such a well-recognized procedure as litholopaxy is dismissed in a foot-note, we cannot consider that the author has brought his work up to date. For the old, classical operation, the description is at once not only clear in diction, but forcible in the impressiveness of the style adopted by the author.

The chapters on tenotomy and operations on nerves are lamentably scanty. The work doubtless is well adapted to the needs of the students who have passed under Mr. Bell's instruction, but for other purposes the surgeon of to-day will find many books that will better answer his needs.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 20, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: $5.00 *per year, in advance, postage paid, for the United States and Canada;* $6.00 *per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 *Boylston Street.*

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 *Boylston Street.*

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

THE FIRST TRIENNIAL CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE First Triennial Congress of American Physicians and Surgeons has been often mentioned in these columns. The meeting, this year, comprises these eleven societies: the Surgical Association, the Genito-Urinary Association, the Laryngological Association, the Climatological Association, the Association of American Physicians, the Otological Society, the Ophthalmological Society, the Neurological Association, the Dermatological Association, the Physiological Society, and the Orthopedic Association. These societies devote the day-time to their respective society meetings, and their programmes have already been published in our pages.

When this number of the JOURNAL reaches its readers, the Congress will have been held. It is apparent that in numbers, at least, it will reach a comparatively high figure for the limited membership of the societies that compose it, and the papers promised show that original and interesting material is to be brought forward.

In one way the Congress ought to interest the profession at large. It is a cause of anxiety to many lest the specialists should lose their attachment to the profession as a whole. This Congress is, as it were, an acknowledgment, on the part of men who are members of the various special societies, of a common interest and a common bond. As they have to a certain degree separated themselves from the general practitioner, they here return, bringing the fruits of their work in their respective fields for the general advantage.

The general meetings take place in the evenings. On Tuesday evening, September 18th, papers on "Intestinal Obstruction in its Medical and Surgical Relations" were to be read by Dr. Reginald H. Fitz, of Boston, and Dr. Nicholas Senn, of Milwaukee, Professor of Surgery in Rush Medical College, Chicago, Ill., followed by a discussion, in which Dr. William Pepper, Dr. J. Collins Warren and Dr. Thomas G. Morton, and others were expected to take part. On Wednesday evening, September 19th, papers on "Cerebral Localization in its Practical Relations" will be read by Dr. Charles K. Mills, of Philadelphia, and Dr. Roswell Park, Professor of Surgery in the Buffalo Medical College, followed by a discussion by Dr. David Ferrier, Mr. Victor Horsley, Dr. W. W. Keen, Dr. E. C. Seguin, Dr. Robert F. Weir, and others. Thursday evening, September 20th, is to be devoted to the address, by the President, John S. Billings, M.D., U. S. A., on "Medical Museums," followed by a general reception in the United States Army Museum Building. The JOURNAL is delayed to give our readers the address, which will be found in full in our pages.

The address of the President illustrates the remarkable faculty, which shows itself in all Dr. Billings's addresses, of including the medical world in his vision, and making its several countries contribute to the instruction of his auditors: and the true brotherhood of science and the kinship of nations seems realized as he compares the distant and time-honored medical institutions of the old world with those of our own country.

The functions of medical museums in general and of the Army Medical Museum in particular, will doubtless be better understood than before. What Dr. Billings has to say concerning the relation of the Army Medical Museum to the public will surprise the majority of those who hear or read his speech. That non-medical people should be admitted to a medical library in any way save by stealth, has never entered into the ideas of most of us. But that there ought to be an opportunity for those who desire to learn something about themselves, most physicians will doubtless admit when the subject is fairly presented to them; and if such a function belongs to the National Medical Museum, will it not presently be seen to belong also to other museums of a similar nature? This is to be — not improbably — one of the ways in which the public is to be educated up to a point where education will be a necessity on the part of the man who professes to give medical advice. We shall give our readers an opportunity to read for themselves the proceedings in subsequent numbers.

YELLOW FEVER, SOUTH AND NORTH.

THE sad case of Professor Richard A. Proctor has naturally excited extraordinary attention from the prominent position of the patient in the world of astronomical science. It seems to have been a typical one of yellow fever, and yet it is certainly remarkable that, so far as known, there has been no yellow fever at Oak Lawn, Marion County, Florida, from whence he came to New York. He arrived at the latter city on Monday, the 10th instant, having travelled through by rail. To this long journey he ascribed the indisposition he felt on going to bed at the Westminster Hotel at Irving place and Sixteenth Street. On Tuesday morning he was much worse, and was ad-

vised to consult Dr. George S. Conant, who formerly was an inspector of contagious diseases in the health department. Dr. Conant examined Prof. Proctor, and sent word for Dr. Cyrus Edson, chief inspector of contagious diseases. The two experts made a careful examination, and also called Dr. A. Jacobi in consultation, knowing that he had had experience in yellow fever cases.

Prof. Proctor had a high fever and his skin had a yellowish color. He also vomited at intervals, but the physicians could not be certain that he was suffering from yellow fever. He told the physicians that he had not been near Jacksonville or any other yellow fever centre, and, so far as he knew, had not been exposed to the disease. A clean bill of health had been given to him when he left Florida. The physicians decided that he ought to be removed to the Willard Parker Hospital, to which he cheerfully consented on being told of their suspicions, but said he was confident the disease would not prove to be yellow fever. During Tuesday he steadily improved, was able to walk, and stood well his transportation in an ambulance. That night he rested well, but early the next morning came a relapse, attended by the "black vomit," convulsions and death. Every possible precaution was observed by the officers of the Board of Health, and no fear is apprehended that any other cases of the disease will arise in the city from this source.

On account of the public interest in this case, and for the purpose of allaying any uneasiness that might be felt as regards possible future danger, President Bayles has had the following memoranda regarding yellow fever in New York prepared by the statistician of the Board:

"In 1856, between April 10th and October 4th, seventy-nine infected vessels from infected ports arrived in the Bay of New York, and anchored for four miles above and below the Narrows, between Long Island and Staten Island, from Gravesend Bay to within a short distance of New Brighton. The fever extended to the land along the borders of each island opposite the line of infected vessels, and no farther, except one spot on the south side of Governor's Island and about opposite on the New Jersey shore. Thirteen deaths from the disease occurred in New York, but the victims had all been infected outside of the city, and no case originated either in New York or Brooklyn. During July, August and September, sixty-four cases occurred on Governor's Island, and several hundred along the shores of Long Island and Staten Island.

"In 1870 occurred the last appearance of the disease in an epidemic form in this vicinity. It was practically confined to Governor's Island, where, out of a population of 774, there were 159 cases and 52 deaths. The first case was reported August 13th, and the last October 26th, the last death being on October 29th. On October 1st the sick were removed from Governor's Island to quarantine. It is to be noted in connection with the question of contagion that twenty-nine cases occurred among those left behind in the infected district, while the sick taken to quarantine station, eighty-two in number, did not communicate the disease to a single individual. Eleven patients who contracted yellow fever on the Island and sickened in the city of New York (of whom nine died) did not in any instance communicate the disease, though quartered in crowded, filthy parts of the city. Only three deaths from cases of yellow fever were reported in the annual report of the Board of Health for 1870, because the earlier cases were not properly diagnosticated. No deaths from this cause were reported on doctors' certificates until October 2d, when, as a fact, there had been six previous cases reported as typhus fever, remittent fever, pernicious fever, hepatitis, coma and paralysis. The disease had been prevailing on Governor's Island since August 13th, but the first death occurred in the city on September 9th. No suspicion was aroused even in the city till September 13th, and the diagnosis of the epidemic was not made sure even on Governor's Island until September 27th."

The progress of yellow fever in Jacksonville during the past week is shown by the following official statistics. The total cases up to September 9th, were as we reported last week, 604, with 73 deaths.

"For twenty-four hours ending 6 P. M., September 10th, new cases, 32; deaths, five. September 11th, new cases, 48; deaths, 11. September 12th, new cases, 59; deaths, 10. September 13th, new cases, 44; deaths, 4. September 14th, new cases, 43; deaths, 12. September 16th, new cases, 74; deaths, 9. September 17th, new cases, 52; deaths, 6. September 18th, new cases, 156; deaths, 20. September 19th, new cases, 130; deaths, 14, Total to yesterday morning, 1,333; deaths, 170."

Among the dead are the chairman of the committee on sanitation of the Citizen's Association. About 65 cases had been reported at McClenny up to September 14th, with 10 or 12 deaths. The disease appeared among the refugees at Hendersonville, N. C. Six cases developed at Gainesville, among the members of the Gainesville Guards who lately went to suppress the longshoremens' riot at Fernandina.

Yellow fever was reported as present in New Orleans, and a quarantine against that city was established at Galveston; but the Louisiana State Board of Health promptly came out in the following denial and protest:

"We give positive assurance that there is no yellow fever in New Orleans. There has not even been a suspicious case this summer. Should a case occur you will be immediately notified, in accordance with the pledge entered into between the boards of health of the Gulf States."

The Governor of Texas distrusting this assurance, has refused to remove the quarantine.

The weather during much of the past week in Jacksonville was wet and hot, and the ground steamed freely. Fourteen nurses, sent by Harry Miner of New York, arrived September 16th, and twenty-three nurses from New Orleans. Several of these, especially those from New York, were unacclimated, and were to be returned home. None but acclimated and experienced yellow fever nurses and physicians are desired.

THE GERMAN TREATMENT OF OBESITY.

DR. I. BURNEY YEO, in the current number of the *Nineteenth Century*, discusses the Schweninger (Oertel) treatment of obesity, now popularized in Germany by a brochure which has gone through sixteen editions.

This system of treatment, which can hardly be said to be Schweninger's, being borrowed principally from Oertel, is directed mainly against the prevalent tendency (especially in Germany) to morbid obesity — in other words, to getting too fat. Dr. Yeo asks two practical questions: (1) Is there any harm in getting fat? (2) When may a man be said to be getting too fat? and in reply to the first question, remarks that a very fair share of health and activity is not inconsistent, in some constitutions with a considerable amount of obesity. "As far as longevity is concerned, it may be some comfort to know that the tables of some of the American life insurance offices show that it is better to be much above the average weight than much below it; but it is better to be neither." He adds, however, that a great excess of weight due to an increased formation of fat is an abnormality closely bordering on disease. Such excess of adipose is, he says, almost always due to excess in eating, and fat persons who would get thinner should realize this fact. "A daily deposit of a quarter of an ounce of fat will, in ten years, increase the weight of the body by fifty-seven pounds." Excess of food includes excess of the albuminous group (which has been proved to be fat-forming as well as flesh-forming), as well as the carbo-hydrates (fatty, starchy and saccharine foods). In the young and active, the food which they consume is appropriated in the building up of their tissues, and to the development of muscular and nervous energy; there is little or no excess or waste. When the age of growth has come to an end, but is succeeded by an active and vigorous life, food is needed to develop as much muscular and nervous energy as before, or more, but the food needed for growth is needed no longer. But when the period of growth and activity is succeeded by a life of inactivity or indolence or self-indulgence, then, if the same amount of food is taken as was consumed during the period of growth and vigorous exercise, there is a superfluity, which in some cases is deposited and accumulates in the organism in the form of an excessive amount of fat.

The consumption of alcohol favors polysarcia; so also does an indolent, inactive, luxurious life. Alcoholic stimulants restrain waste on well-known principles, and an indolent life promotes accumulation of force making materials far in excess of expenditure.

Dr. Yeo considers the "Banting" system, and objects to it that it rests on an erroneous scientific foundation, which overlooks the fact that fat can be formed out of nitrogenous food, out of the lean of meat, for instance, as well as out of carbo-hydrates. "Not only does it often induce subjective feelings of discomfort and bodily feebleness, a great loathing of the constant and exclusively meat diet, as well as digestive disturbances, which necessitate its interruption, but it fails, in the more serious cases, to relieve the feebleness of the heart, the tendency to congestion of the lungs, and even dropsy, which complicate the graver forms of excessive corpulency." Ebstein's "cure" allows all kinds of fatty food — the fat of meat, butter, cream, fatty sauces and soups, but prohibits the carbo-hydrates, such as sugar, potatoes, and all forms of starchy food, and of bread, permits at most, three and a-half ounces a day. All kinds of meat in small quantity, as well as asparagus, spinach and cabbage are permitted. Dr. Yeo remarks that the success which has attended the Ebstein method must be referred mainly to the abstinence from the carbo-hydrates which it enforces, but it is hardly sufficiently supporting, and fails to relieve the heart-disturbances which attend extensive obesity.

The Schweninger (or rather the Oertel method) not only provides for the removal of excess of fat, but it also prevents its reaccumulation, and at the same time restores tone to the organs of circulation, which so often, in cases of excessive obesity, is lost. Oertel's system agrees with those above given in reducing the carbo-hydrates in the diet of the obese. It allows more fat than the Banting formula, and nearly twice as much albuminous food as Ebstein's, less than half as much fat as the latter, and about twice as much carbo hydrates. "This amount of fat and carbo-hydrates is admissible in those cases where active exercise can be and is taken, as muscular exertion is attended with a considerable destruction of fat, and the relative excess of albuminous food in this formula leads to the displacement of the fat accumulated in the substance of the muscles, and to a new formation of muscular tissue in its place. At the same time, this diet protects the nitrogenous tissue from waste, a condition of health which is lost sight of in Ebstein's method. Indeed, the central idea in this cure is to *strengthen the muscle of the heart*, and this is aimed at, not only by a carefully considered dietary, but by the prescription of regular active bodily exercise and suitable gymnastics."

This method is somewhat modified in the management of those grave cases where the accumulation of fat about the heart has led to great embarrassment or perhaps degeneration, of that organ, and to consequent visceral congestion, and even to dropsy. In such cases, the fat and carbohydrates of the food is still further reduced, and the amount of fluid consumed is severely restricted, and perspiration is promoted by vigorous bodily exercise, especially in climbing graduated ascents. The following, then, are the objects aimed at in this cure:

(1) To improve the muscular tone of the heart.

(2) To maintain the normal composition of the blood.

(3) To regulate the quantity of fluid in the body.

(4) To prevent the deposit of fat.

These objects are attained by the following means:

(1) The muscle of the heart is strengthened by enforced exercise, such as *climbing heights*. This re-

quires great care, and the exercises must be *graded*, the amount of work being increased as the patient can bear it.

(2) To preserve the normal composition of the blood, the food should be chiefly albuminous. It may consist of the lean of roast, or boiled beef, veal, mutton, game, and eggs. Green vegetables (as cabbage or spinach, may be taken; fat and carbo-hydrates only in very limited quantities; from four to six ounces of bread per diem.

(3) To regulate the quantity of fluid in the body the amount of fluid drunk daily must be limited. One cup (rather less than six ounces) of coffee, tea, or milk morning and evening, and about twelve ounces of wine, and from eight to sixteen ounces of water shall comprise all the fluid consumed in twenty-four hours. Beer is entirely forbidden. The discharge of fluid from the body is promoted by active exercise and occasionally by a course of baths, with packing.

(4) To prevent the deposit of fat the principles of diet already set forth must be carried into practice as follows:

Morning.—One cup of tea or coffee with a little milk, altogether, about six ounces; bread about three ounces.

Noon.—Three to four ounces of soup, seven to eight ounces of roast or boiled beef, veal, game, salad or a lighter vegetable, a little fish (cooked without fat) if desired, one ounce of bread or farinaceous pudding (never more than three ounces), three to six ounces of fruit, fresh preferred, for dessert. It is desirable at this meal to avoid taking fluids, but in hot weather, or in the absence of fruits, six to eight ounces of light wine may be taken.

Afternoon.—The same amount of coffee or tea as in the morning, with, at most, six ounces of water, an ounce of bread as an exceptional indulgence.

Evening.—One or two soft-boiled eggs, an ounce of bread, perhaps, a small slice of cheese. Salad and fruit, six to eight ounces of wine, with four to five ounces of water.

Such, briefly summarized, are the principles of this peculiarly German anti-fat regimen, for which, as Dr. Yeo rightly affirms, the credit almost entirely belongs to Professor Oertel, the main features of it having for years been set forth in his writings. These principles seem to commend themselves as sound, though their practical application will require continued modification to adapt them to the stage of the affection, to the constitution and habits of the patient.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 8. 1888.

Cities.	Estimated Population for 1888.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,819: under five years of age 1,373; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 828, consumption 288, acute lung diseases 189, diarrhœal diseases 436, diphtheria and croup 122, typhoid fever 100, whooping-cough 56, malarial fever 49, scarlet fever 32, measles 11, puerperal fever 11, cerebro-spinal meningitis eight. From whooping-cough, New York 23, Brooklyn eight, Washington seven, Chicago and New Orleans four each, Baltimore and Cambridge three each, Philadelphia and Pittsburgh two each. From malarial fevers, New Orleans 15, New York seven, St. Louis nine, Baltimore six, Brooklyn and Washington four each, Philadelphia two, Nashville and Charleston one each. From scarlet fever, New York 19, Brooklyn five, Philadelphia and Chicago two each, Baltimore, Boston, Nashville and Pittsburgh one each. From measles, New York eight, Philadelphia two, Chicago one. From puerperal fever, New York seven, Brooklyn two, Washington and Charleston one each. From cerebro-spinal meningitis, New York three, Chicago and St. Louis two each, Haverhill one. From erysipelas, Baltimore two, Brooklyn one. No deaths from small-pox.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273 for the week ending September 1st, the death-rate was 17.5. Deaths reported 3,153: infants under one year 1,047; acute diseases of the respiratory organs (London) 130, diarrhœa 379, measles 53, whooping-cough 52, diphtheria 35, scarlet fever 22, fever 29, small-pox (Preston) two.

The death-rates ranged from 10.1 in Plymouth to 25.3 in Leeds; Birmingham 17.1; Bradford 15.2; Bristol 11.5; Hull 16.5; Leicester 21.0; Liverpool 19.7; London 16.4; Manchester 24.1; Nottingham 12.0; Portsmouth 20.6; Sheffield 18.3; Sunderland 20.6.

In Edinburgh 15.1; Glasgow 17.5; Dublin 20 4.

The meteorological record for the week ending September 8, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Week ending	Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.		Velocity of Wind.		State of Weather.[1]		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. A., FROM SEPTEMBER 8, 1888, TO SEPTEMBER 14, 1888.

JARVIS, NATHAN S., first lieutenant and assistant surgeon. Is granted one month extension of leave of absence, on surgeon's certificate of disability. S. O. 210, A. G. O., September 10, 1888.

CALDWELL, DANIEL G., major and surgeon. Is granted two months' leave of absence from September 14, 1888. S. O. 210, A. G. O., September 10, 1888.

BANISTER, JOHN M., captain and assistant surgeon U. S. A. Is granted two months' leave of absence, with permission to apply for an extension of one month, to take effect when his services can be spared. S. O. 211, A. G. O., September 10, 1888.

NORRIS, BASIL, lieutenant and medical director. Will proceed to Fort Klamath, inspect the medical department at that post, and upon completion thereof return to these headquarters, (Department of the Columbia, Vancouver Barracks, W. T.) S. O. 103, September 3, 1888.

PAGE, CHARLES, colonel, assistant surgeon general and medical director of the department Will proceed to Forts Riley and Hays, Kansas, Post near Denver, and Forts Crawford, Lewis and Lyon, Col., and return on public business. The travel enjoined is necessary for the public service. Headquarters Department of the Missouri, Fort Leavenworth, Kansas, September 1888. S. O. 114.

AINSWORTH, FRED C., captain and assistant surgeon. Will, by direction of the Secretary of War, proceed to Kennebec Arsenal, Augusta, Me., on public business connected with the Medical Department of the Army, on completion thereof, will return to his station in this city, Washington, D. C. S. O. 211, A. G. O., September 11, 1888.

STRONG, NORTON, captain and assistant surgeon. By direction of the acting Secretary of War, will report in person at 11 o'clock, A.M., October 18, 1888, to Brig. Gen. John R. Brooke, president of the retiring board in session at Omaha, Neb., to give testimony in a case pending before the board. Upon completion of this duty he will return to his proper station. By paragraph 9, S. O. 212, A. G. O., September 12, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING SEPTEMBER 15, 1888.

LUNG, GEORGE A., assistant surgeon. Ordered to Receiving-ship "Vermont," Navy Yard, New York.

ERRATUM.

In the obituary notice of the late Dr. G. D. Townshend, it should have been stated that he was a graduate of the University of Pennsylvania, and received his degree in 1865.

BOOKS AND PAMPHLETS RECEIVED.

A Eulogy upon Cornelius Rea Agnew, read before the New York Academy of Medicine, by T. Gaillard Thomas, M.D. June 7, 1888.

Considérations Cliniques sur le Traitement du Catarrhe Chrodique des fosses Nasales. Par le Docteur Léonce Lacoarret, a Salies-de-Béarn. Paris. MDCCCLXXXVIII.

Report of Ten Cases of Pleuritic Effusion with Aspiration of the Chest — Fourth Series — With a Case of Injection of Carbolized Iodine into a Lung Cavity. By F. Peyre Porcher, M.D., one of the physicians to City Hospital, Charleston. Reprint. 1888.

A Case of Poisoning by Sulphate of Atropia; Recovery. By Blewellyn Eliot, M.D., Washington, D. C. Reprint. 1888.

New York State Board of Health. Eighth Annual Report to Legislature, February 27, 1888. Troy Press Co. 1888.

Therapeutics: Its Principles and Practice. By H. C. Wood, M.D., LL.D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System, in the University of Pennsylvania. A work on medical agencies, drugs and poisons, with especial reference to the relations between physiology and clinical medicine. Seventh edition of a Treatise on Therapeutics, rearranged, rewritten and enlarged. Philadelphia: J. B. Lippincott Co. London: 10 Henrietta St. 1888.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry; a Text-Book especially adapted for Students in Pharmacy and Medicine. By W. Simon, Ph.D., M.D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons, Professor of Chemistry and Analytical Chemistry in the Maryland College of Pharmacy, Baltimore, Md. Second edition, revised and enlarged; plates and illustrations. Philadelphia: Lea Brothers & Co. 1888.

Original Article.

SHOCK.[1]

BY DAVID W. CHEEVER, M.D., OF BOSTON.

THE operative surgery of our time has annulled pain temporarily, arrested hæmorrhage permanently; averted septic absorption. It has not prevented shock. This is still a cause of much fatality. It is the object of this paper to inquire whether modern surgical procedure has *diminished* shock; wherein it fails to do so; and to suggest improvements of its defects.

What is shock?

When any one gropes his way in a dimly lighted passage, and meets unexpectedly a strange person at some turning, he experiences a start, a mental apprehension, his heart turns over, flutters, but at once recovers its balance. Pursuing his path, if he now, in descending, misses a step in the dark, he has a greater shock to his nerves, he braces himself, flutters, sweats, or is chilled. If he falls and bruises himself moderately, he has vertigo, nausea, cold sweat, pain. If he falls and breaks open a joint, he has syncope, epileptiform convulsions, nausea, fluttering pulse, sweat, pain. If he injures himself more severely, he has unconsciousness.

This is a simple description of the degrees of shock:

Apprehension,
Fluttering,
Sweating,
Chilliness,
Pain,
Vertigo,
Nausea,
Faintness,
Convulsions,
Unconsciousness,
Collapse.

The phenomena of a fainting-fit are the phenomena of shock. Sudden, disagreeable, painful, destructive impressions produced on the surface or efferent nerves, and affecting the brain; thence the ganglionic system; then the heart, the stomach, the skin; and thus the brain, at last.

Moderate shock terminates in reaction. This is the *recoil* of the system. It restores the balance; but the pendulum which marks the nervous force, swings back beyond the normal line. We have temporary fever, flush, full pulse, excitement.

Severe shock is more lasting. The pulse vibrates, intermits, flags, rallies, flags again, is soft, compressible, uncertain; faintness is constant, but partial; vomiting occurs; cold extremities; dilatable pupils; pallor; imperfect reaction; very slow recovery; a condition where a feather turns the scale against the patient.

If now an operation is done, we have renewed shock, prolonged shock, secondary shock; a matter of days rather than hours; persistent nausea; exhaustion; lowered temperature; diarrhœa; imperceptible and gentle death. Or, if an old person, that state known as prostration with excitement; typhoidal delirium, a dusky flush over the malar bones, dull eyes, intermittent pulse, jactitation, exhaustion, death.

[1] Read before the American Surgical Association; at the First Triennial Congress of American Physicians and Surgeons, at Washington, September 20, 1888.

Primary shock, reaction; early and perfect; or slow and imperfect. Secondary shock: prostration, nausea, excitement, collapse. Loss of blood, from accident or operation, adds to the shock or complicates its symptoms.

Jar, crushing, mutilation, pain, cutting, bleeding, chilling, all act on the nervous centre; react on the ganglia, the heart, the power of breathing, the temperature, the consciousness, the life.

Given then the problem and the phenomena of shock, what particular influences have the operative procedures of *modern* surgery upon them?

They may be summed up in three points:

The effects of anæsthetics;
The effects of the operations;
The effects of the dressings.

These all belong together and affect each other.

Anæsthetics annul pain, but end in nausea.

Operations under anæsthetics are needlessly prolonged and exhausting.

Modern dressings are tedious and chilling.

Have we lessened, or added, to shock by modern surgery?

Pain and bleeding are *less*. Slow cutting, nausea, exposure, low temperature are *more*. Primary shock is diminished: secondary shock is increased.

Formerly the time consumed in an operation was short. An amputation was hurried, now it is deliberate; an abscess was incised, now it is aspirated and curetted; a joint injury was cut off, now it is excised; the peritoneum was peeped into, now it is boldly explored; the bladder was cut for stone, now it is a prolonged crushing and washing; a breast was amputated, now the axilla is formally dissected. The old method was a matter of minutes; now it is one of hours.

Patients are frequently from one and a half to two hours on the operating table; and three hours in recovering consciousness so that they can swallow. Do we realize what this prolonged cutting, pinching and dissecting mean to the nervous system after anæsthesia is past? Does not the long exposure of the great veins to the air, in dissecting tumors, increase coagulability and future infarction? Can the peripheral nerves be lacerated *seriatim* without exhausting their constitutional irritability? It is recognized that long continued and large dissections on the front and sides of the neck are especially fatal.

Operations of *secondary* magnitude are now so prolonged that I have repeatedly seen patients die of primary shock, or *repeated shocks*, where the patient was one to two hours under the knife. It is said that he had not the vitality to resist. He had not; but consider what a perineal section, scooping out a uterine tumor, curetting a bladder, removing glandular enlargements, sometimes involve in time, in exhaustion, in capillary oozing, in shock.

Equally unphilosophical and fatal is the practice of operating in cases of primary shock before reaction has come on. An amputation is begun in half-life, and ended in death. Especially difficult to decide are the cases where the patient reacts imperfectly, and relapses. These cases are easily made fatal, and only saved by quick amputations, slight exposure and short anæsthesia. The golden moment of fairly established reaction must be seized, before traumatic fever sets in. This moment comes in from six to eighteen hours after the injury, or it never comes.

It should be considered an *axiom* that anæsthesia does not diminish existing shock, but only annuls the additional shock which the pain of cutting produces. It prevents the pain of an operation from increasing the shock which may be present from an injury. It prevents the pathological case from experiencing the shock produced by the pain of cutting out a tumor; it does *not* prevent the secondary shock of the mutilation; it adds to secondary shock if the anæsthesia is prolonged.

In feeble subjects the lack of nourishment which precedes an operation, desirable on account of safe anæsthesia, is much aggravated by their inability to retain food after the operation. This has an important influence in bringing about collapse.

Lowering of the bodily temperature is constant after an operation under anæsthesia. The thermometer frequently falls to 97°, to 96°, and after severe and prolonged operations, to 95° Fah. This is a very serious matter, and has a marked influence in delaying reaction from shock. This chilling of the vital heat is induced, first, by anæsthesia, which, if prolonged, ends in a dripping sweat; next, by careless exposure during an operation. Then also it is largely due to antiseptic irrigations, to vapor douches of similar agents, to applications of cloths wet in corrosive or carbolic solutions around the site of the operation. The axillæ, the neck, the thorax and the abdomen are especially prone to deleterious chilling in this way.

Evaporation is a great factor in reducing heat; and this is constantly occurring on the body of the patient, in a warm atmosphere, during a prolonged operation. Especially is this dangerous when the peritoneal surfaces are exposed; evaporation then is very rapid and very extensive.

Warm douches and washes give as great a subsequent chilling as cold ones, as all experience who take a tepid bath.

The sufferer is frequently allowed to lie about too long, under an anæsthetic, waiting for his turn, in busy hospital practice.

The surgical toilette of wounds, in the modern modes of dressing, is depressing, exhausting, devitalizing.

Finally, comes the greatest evil of all, nausea. Nausea is one of the marked symptoms of severe shock, primary or secondary. Unfortunately, anæsthetics very frequently produce this as a secondary effect.

Persistent vomiting and retching mark the slow sinking and collapse of secondary shock after capital operations. Continued nausea is one of the worst of symptoms; begun in pain, and shock, it recurs after anæsthesia, and continues as the most dangerous factor in preventing reaction.

What can we do to prevent or diminish shock?

(1) Wait for reaction.

(2) Never neglect to calm those suffering mental shock by a cheerful word and personal presence.

(3) Give alcohol, either spirits or wine, a quarter of an hour before the anæsthetic.

(4) Make the anæsthesia short; never begin it until everything is ready; suspend it during the less painful dressings. Consciousness returns *tardily*. We keep up the anæsthetic longer than is necessary.

(5) As rapid an operation as can prudently be done.

(6) As short a dressing as is practicable.

(7) As a cardinal point, avoid *chilling* the patient.

To promote reaction after the operation:

(1) Persistent and *carefully* applied *dry* heat. (Be *over*-careful about accidental burns.)

(2) Liquid nourishment, combined with a stimulant and a little laudanum, by enema.

(3) Subcutaneous injection of brandy.

(4) Aromatic spirits of ammonia by the mouth. Champagne is sometimes retained when other things are rejected.

(5) Black coffee and brandy, the stimulant *par excellence*, when it can be retained on the stomach.

(6) Quiet: a horizontal, or more than horizontal position; sleep; assurance that all is over, and doing well.

Modern surgery has won *three* great triumphs:

It substitutes sleep for pain.

It averts secondary hæmorrhage by the animal ligature.

It prevents fermentation by germicidal applications.

Can we add a *fourth*, by stilling the nervous system, and averting, or diminishing secondary shock?

Reports of Societies.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE First Triennial Meeting of the Congress was held in Washington, September 18, 19, and 20, 1888.

FIRST SESSION, TUESDAY.

The meeting to receive the report of the Executive Committee and for Organization was held at one P. M., Tuesday in the Grand Army building.

The meeting was called to order by DR. WILLIAM PEPPER, Chairman of the Executive Committee, who spoke as follows:

"On behalf of the Executive Committee I have to announce the manner in which we have discharged our responsible duty. The present meeting is the result of prolonged deliberation which began to take shape more than four years ago, before the attention of the medical profession became occupied with preparation of the meeting of the International Medical Congress, but all action was deferred in order that there should not be the semblance of interference with that important meeting. This delay has served to render more conspicuous the necessity for this organization.

"In order to produce the best scientific results, it is essential that the members in attendance shall be reasonably limited, and that as far as possible the same men shall attend successive meetings, securing a continuity of intellectual life and activity. A large proportion of those interested in the development of such an organization, are, as I am myself, warmly attached to the American Medical Association, and determined to exert their influence to maintain and promote the means of this great national organization.

"Your committee ventures to hope that their provisions will meet the unanimous approval of the Congress. We have recommended that the sessions shall be triennial. We have jealously guarded against the admission of parliamentary business, since the functions

of the Congress are designed to be absolutely or exclusively scientific. We have also guarded the independent sovereignty of each participating society.

"Lastly, the Executive Committee has reached the conclusion that the selection of the President of each Congress shall be entrusted to the Executive Committee then in office. Close study of the conditions of this Congress has led the committee to feel that if this organization were to have the effect of favoring the multiplication and subdivision of special societies, it would be nothing less than a calamity. We have therefore provided that the admission of new associations shall be secured only by the unanimous vote of the Executive Committee.

"It remains only to add that in exerting the privilege of selecting a President for the first Congress of American Physicians and Surgeons, we feel that we have been guided to the choice of a man, whose admirable personal character, whose high attainments, and whose illustrious services in the cause of literature, of science and of the entire medical profession mark him as entitled to this great honor and distinction.

"It gives us therefore the utmost gratification to present to you our President, Dr. John Shaw Billings, and to announce that the Congress of American Physicians and Surgeons is now duly organized."

President Dr. J. S. Billings then took the Chair, and responded in a brief address.

THE ADDRESS OF WELCOME

was delivered by Dr. Samuel C. Busey, of Washington.

The consideration of

THE BY-LAWS

was next taken up.

(1) This organization shall be known as the Congress of American Physicians and Surgeons.
(2) It shall be composed of National Associations for the promotion of medical and allied sciences.
(3) It shall hold its sessions triennially in the City of Washington, D. C.
(4) The officers of the Congress shall be a President, Vice-Presidents, a Secretary, a Treasurer, and an Executive Committee.
(5) The President shall be elected by the Executive Committee, of which he shall be *ex officio*, member. He shall preside at the sessions of the Congress. He shall deliver an address.
(6) The Presidents of the participating societies shall be *ex officio* the Vice-Presidents of the Congress.
(7) The Secretary and Treasurer shall be elected by the Executive Committee. They shall be *ex officio* members of the Executive Committee.
(8) The Executive Committee shall be composed of one member from each participating society: and said members shall be elected by the various societies at the next annual meetings subsequent to the Congress. It shall be charged with all duties pertaining to the organization of and preparation for the ensuing Congress, including the election of all officers, and for a Committee of Arrangements. It shall superintend the publication of the Transactions of the Congress.
(9) The expenses of the Congress shall be divided between the participating societies in proportion to their membership.
(10) The admission of new Associations to participation in the Congress shall be by unanimous vote of the Executive Committee.

These by-laws were unanimously adopted.

EVENING SESSION, TUESDAY.

President, Dr. J. S. Billings, in the Chair.

THE MEDICAL RELATIONS OF ACUTE INTESTINAL OBSTRUCTION,

by Reginald H. Fitz, M.D., of Boston.

The subject of this paper was the diagnosis and medical treatment of the acute internal, mechanical varieties of intestinal obstruction. The only causes recognized were strangulation from adhesions, vitelline remains, peritoneal slits, pockets and rings; intussusception, twists and knots; abnormal contents, strictures and tumors. The evidence presented resulted from an analysis of 295 cases collected from medical literature since 1880.

The most constant symptoms of obstruction were shown to be pain, vomiting, tympany and tumor. Stoppage of the bowel was not regarded as the most essential symptom in diagnosis, since frequent loose stools characterize intussusception and may occur in other varieties of obstruction. Too much attention directed to this symptom leads to erroneous diagnosis, since it is of frequent occurrence in peritonitis and often results in irrational and injurious treatment.

The physician is called upon to decide whether the given case is one of acute obstruction; then where its seat and what its cause, and finally what is to be done. The evidence offered, showed that the diagnosis was to be made by excluding the various causes of peritonitis. Its seat in the large or small intestine was to be determined by injections under high pressure when necessary. The variety was for most practical purposes, an intussusception; or a twist of the large intestine and strangulation, or gall stones in the small intestine. The differential diagnosis depended on the relative frequency of these varieties, the age of the patient, the antecedents and immediate symptoms.

The treatment consisted in the attempt to relieve intussusception of the large intestine by forced injection under anasthesia with massage, and to treat obstructing gall stones by opium, possibly by the aid of laxatives and electricity. All the other varieties of acute obstruction require surgical treatment. The latter treatment is also necessary on or before the third day in cases of intussusception not yielding to forced injections and in gall stones when the symptoms become urgent.

THE SURGICAL TREATMENT OF INTESTINAL OBSTRUCTION,

by N. Senn, M.D., of Milwaukee.

He claimed at the very beginning that all cases of true intestinal obstruction are, in every sense of the word, surgical affections. Intestinal obstruction is present when from mechanical or from dynamic causes the intestinal canal becomes completely or partially imperforate, interfering completely or partially with fæcal circulation. It is important that a distinction be made between the cases due to mechanical causes and those due to dynamic causes. In the former the surgeon is expected to modify the mechanical cause. In the other the surgical treatment is limited to diminishing intra-abdominal pressure. Cases of internal intestinal obstruction should be considered in the same light as cases of strangulated hernia. The time that such a case may safely be permitted to go without operation varies. In some, twenty-four hours will suffice for the occurrence of irreparable pathological changes; in others a much longer time may be allowed to elapse. Operation should be performed as soon as the diagnosis is made.

The surgical resources in the treatment of internal obstruction were taken up seriatim.

Irrigation of the Stomach was first referred to. All forms of intestinal obstruction, no matter what the cause, are aggravated by anything that increases the

hydrostatic pressure on the proximal side of the obstruction. Irrigation of the stomach relieves this, and also diminishes the intra-abdominal pressure. It not only empties the stomach, but evaçuates the contents of a number of feet of the intestine. It, however, will not do to rely upon this as a radical measure, except when the cause of obstruction is of a temporary character. This measure should always be performed before operation, as it prevents vomiting. An antiseptic solution should be used in the irrigation.

Distension of the Intestine with Fluids. The mechanical effects of this measure are limited to the colon. The fluid does not pass beyond the ilio-cæcal valve. Why should we not in these cases resort to the lightest possible substance known, hydrogen gas, which is harmless, readily obtained and aseptic. A pressure of one-fourth to two pounds to the square inch overcomes the resistance of the ileo-cæcal valve, and forces the gas from the anus to the mouth. A pressure of eight to ten pounds to the square inch is required to produce palpable injury of any of the coats of the intestine. If perforation takes place there is at once a positive indication for opening the abdomen. The fact that perforation has occurred is known by the disappearance of the liver dulness.

Manual Exploration by the rectum is a useful diagnostic and therapeutic measure where the obstruction is below the sigmoid flexures, provided the surgeon has a small hand.

Taxis and Massage should be limited to cases where the obstruction is due to intra-mural causes, and to a few cases of invagination. Uniform uninterrupted equable *pressure of the abdomen* is useful in preventing hyper-distension in these cases, especially where dynamic causes are feared.

Enterostomy, so frequently practised in the past, he hoped, had become very nearly obsolete. It should only be employed where it is clear that the patient will not be able to pass through the ordeal of laparotomy.

Lumbar Colotomy. In cases where the operation was formerly employed we can often, by uniting the portion of bowel above the obstruction with that below by means of decalcified bone plates, avoid the necessity for colotomy. I have specimens showing that a dilated, congested bowel can be repaired when excluded from the fæcal circulation in this way.

The author had in the past eight months preformed gastro-enterostomy in four cases by this method. In all of these cases the operation was a success, although in one case the patient died because the operation had been postponed too long. In one case following, the advice of Leucke had been followed, and the first presenting portion of the bowel had been fastened to the stomach. The patient continued in good condition for nine days, when symptoms of obstruction came on, and he died in three weeks. It was found that the connection with the bowel was eight feet below the pyloric orifice, and that the movements of the bowel had produced a sharp flexion of the intestine, causing obstruction. Gastro-enterostomy in incurable carcinoma is a safe operation, and one which the surgeon owes to all such patients.

[The time allotted to this portion of the discussion having expired, the speaker was unable to complete his remarks.]

DR. ARTHUR DURHAM, of London, had taken much interest in this subject. There is no class of cases which are more serious or more dangerous than those of intestinal obstruction. I agree with Dr. Senn, that usually in these cases the sooner the surgeon is called the better. As soon as the diagnosis is made the operation should be performed. In some cases it should be done before a positive diagnosis is reached, and in order to clear up the diagnosis. Under such circumstances the surgeon must be prepared to meet the indications that present themselves. In trying to reach a diagnosis the probabilities in favor of this or that condition, based upon statistics, should not influence us; but the case should be studied on its own merits, and treated on the indications before you. In regard to the injection of hydrogen gas, he suggested the possibility of the formation of explosive compounds, and thought that atmospheric air might be substituted.

He recommended that in cases of acute obstruction in which there is reason to believe that the cause is in the small intestine, provided the symptoms are severe and urgent, the proper thing, even if an absolute diagnosis has not been made, is to open the abdomen and search for the cause and relieve it as best you can. On the other hand, where the cause is in the large rather than the small intestine, there is not the same degree of urgency. He strongly advocated lumbar colotomy in certain cases. In some cases after colotomy there has been a gradual restoration of the bowel and the patient has recovered completely.

DR. WILLIAM ORD, of London, admitted that there was often a great deal of difficulty in the diagnosis. He was in favor of the views of Dr. Fitz, and claimed a little time before resorting to operation. In some of these cases under the use of hypnotics and time the cause of obstruction had disappeared. Where, however, there is mechanical obstruction the case must sooner or later go into the hands of the surgeon. This time should be a short one. The operation is a serious one, especially in people over fifty years of age. I have often seen the operation performed, and frequently fail in those cases where there was the most reason to expect success.

MR. THOMAS ANNANDALE, of Edinburgh, said that these cases of obstruction should be divided into two classes, the acute and the chronic. In acute cases medical measures should be tried, but not continued too long. If the symptoms are urgent the surgeon should be called at the end of forty-eight hours; the sooner the abdomen is opened the better. In the chronic cases we may wait a considerable time, even until the symptoms become acute. The treatment should then be applicable to a case of acute obstruction. I have largely given up lumbar colotomy, which I have employed more particularly in rectal obstruction, and resort to inguinal colotomy as a simpler and not more serious operation in most cases.

DR. N. SENN, in closing the discussion, stated that there was not the least danger in the use of hydrogen gas. He had performed many experiments on animals and had used the procedure in man. In cases of intestinal perforation it aids the diagnosis, and allows the surgeon to determine whether or not all the openings have been closed. In a recent case of gunshot wound eleven openings near the ileo-cæcal valve were closed, and a twelfth was revealed by the hydrogen gas at the point where the peritoneum is reflected from the bowel to the bladder. The patient is doing well one week after the operation.

THIRD SESSION, WEDNESDAY EVENING.

CEREBRAL LOCALIZATION IN ITS PRACTICAL RELATIONS,

by CHARLES K. MILLS, M.D., of Philadelphia.

In his introductory remarks, the speaker referred to the fact that from the clinical observation of practical physicians sprung the conceptions out of which developed the science and art of cerebral localization. Allusions were made to the discoveries of Bouilland and Broca on speech localization; to the announcement by J. Hughlings Jackson in 1864, that certain convolutions superintended the delicate movements of the hand, which were under the immediate control of the mind; and to Hitzig's researches having originated from his observing certain ocular movements during galvanization of the heads of his patients. Brief reference was made to the history of American work in localization; to the investigations, in 1874, of the New York Society of Neurology and Electrology; to Putnam's discovery that irritation of the white matter beneath definite cortical centres produced movements similar to those caused by irritation of the centres themselves; to the labors of Wood and Ott on the heat centres; and to the light thrown by these investigations upon the mechanism of fever and the action of drugs upon different forms of high temperature.

Before taking up the surgical aspects of the question, the speaker briefly discussed some of the practical results wrought by cerebral localization for psychological medicine and medical jurisprudence; for general symptomatology and diagnosis; and for medical therapeutics and technique.

Trephining for cases of insanity, particularly when guided by the rules of localization, was briefly considered. Two of the recent cases of brain operation reported by Bennett and Gould, and by Macewen, were cited as possibly opening a new field for surgical interference in insanity, the excision of cortical areas as a method of treatment when certain subjective phenomena, such as hallucinations of sight or hearing, can be given a local habitation in the brain.

In turning to the surgical aspect of cerebral localization in its practical relations, the author stated that his remarks would be chiefly concerned with questions of diagnosis. He considered, first, the forms of disease and injury in which cerebral localization is a valuable aid to diagnosis; and, secondly, the topographical diagnosis of the parts of the brain accessible to surgical interference, with some sources of error in such diagnosis. The forms of disease in which such diagnosis has been used are intra-cranial tumors, cysts, fractures, hæmorrhages, abscesses, and discharging cortical areas.

In considering the localization of brain tumors, Dr. Mills referred to twenty cases of autopsies occurring in his own personal experience, in about one-half of which the tumors were in surgically accessible areas, and in, at least, one-fourth of which successful operations might have been performed. He advocated from this experience the excision of old gummata, and also, in special cases, of tubercular growths. The value of localization was shown in cases of fracture when the extent of the unseen damage could not be told by the position and character of the visible lesions.

Of the different forms of intra-cranial hæmorrhage, subdural, cortical, and intra-cerebral were most amenable to localizing diagnosis. The rules for the local diagnosis of these forms of hæmorrhage were then given. Dr. Mills advocated the performance of trephining in exceptional cases of hæmorrhage into the ganglia and capsules, cases in which symptoms indicated that the bleeding had not broken into and inundated the ventricles. From the sections, the best site for operation in such cases, all things considered, would be in the anterior portion of the first or second temporal gyrus. He favored Hughlings Jackson's suggestion of excising localized cortical areas, even when coarse lesions could not be made out, in cases of spasm, beginning locally or deliberately.

The inaccessible areas had been narrowed down by the venturesome surgical explorer, and had become reduced to the middle regions of the base and its bordering convolutions, the corpora quadrigemina, and the pons oblongata.

The characteristics of localizing symptoms were described as phenomena of irritation, destruction, instability, pressure, invasion, and reflex action. Signal symptoms and the serial order of motor phenomena were discussed. Briefly, in certain regions of the brain, an accurate topographical diagnosis could be made with great certainty from positive localizing symptoms. These brain areas include the entire motor zone, in which are embraced the motor or emissive speech area, the region of Broca; the visual area in the cuneus, giving lateral hemianopsia, and the intra-cerebral visual tracts; possibly, also, the angular gyre and the lateral surface of the occipital lobe. In other regions of the encephalon the topographical diagnosis could be made with sufficient accuracy, even for surgical purposes, by the study of the positive symptoms, with, in addition, the application of processes of exclusion and successive differentiation. Particular stress was here laid upon the importance of pressure and invasion symptoms. These areas for approximately certain topographical diagnosis include the cerebellum, the pre-frontal lobe, the temporal lobe, and even certain cranial new districts, as the auditory and facial, when the lesion could be localized within the cranium, between the superficial origin of the nerves and their entrance into their foramina or canals of exit.

Motor localization has become almost an exact science. The latest physiological research bearing upon the subdivision of the motor area, and the light thrown upon the question by surgical operations, were discussed. It was held to be imperative for the neurologist and surgeon to have exact knowledge, not only of the anterior and the posterior limits, but also of horizontal subdivisions of the motor zone.

The old method of subdividing the motor zone into three elliptical or circular areas from above downward was considered insufficient; but the neurologist should be able to locate for the surgeon, from a study of motor phenomena, at least seven or eight positions for trephining; these positions being selected by a close study of the initial or signal symptoms, the serial order of movements, and also of the amount and character of the temporary paralysis after the seizure, and the method of extension of the persisting palsy. Reference was made to operations performed through accurate localization in these areas.

The view of Ferrier as to the localization of the centre for ocular and head movements in the second frontal gyre was concurred in, and observations were cited in its support; when turning of the head and

eyes was the starting point of the spasm, this localization was probably indicated. The fact that cortical oculo-motor palsies were not present as a persistent condition, even with definite lesions of the second frontal gyre, was explained by the intimate and peculiar connections of the oculo-motor nuclei at the base; they do not persist for the same reason that paralysis in the upper distribution of the facial nerve is so seldom permanent. He believed that there was a special centre for the orbicularis palpebrarum movements, probably below and adjacent to the oculo-motor centre.
